Management of established mesh prosthetic infections is based on degree of incorporation, associated soft tissue defects, symptoms, and long-term reconstructive plans. Although biologic mesh is generally accepted for use in contaminated fields, it rapidly loses its integrity when exposed to succus and may be completely lost in the setting of an anastomotic disruption or development of acute ECF. This setting may force debridement of the remaining biologic mesh and planned open abdomen management with complex wound care challenges. PTFE (Gore-Tex) mesh is considered heavyweight microporous and diminishes its ability to incorporate into body tissues, increasing its risk of developing biofilms. Infections involving this type of prosthetic typically involve full explantation. Lightweight and midweight macroporous mesh may be salvaged to some degree. Management of infections of these implants involves debridement of unincorporated mesh and local wound care to optimize rapid granulation and healing. Rarely, these mesh infections may result in long-term sinus tracts that would typically be managed with incision and drainage, prosthetic debridement as needed, and antimicrobial therapy. Fully incorporated mesh typically does not require routine removal. Like management of other soft tissue and deep infections, source control and optimal wound management are key.

Enteroatmospheric and Enterocutaneous Fistulas

Prevention of EAFs and ECFs is a critical component of managing the open abdomen. Prompt abdominal wall closure (before 8 days), use of plastic sheeting and omentum to protect the bowel from contact with temporary closure devices (especially when using NPWT), and covering enteric anastomoses with other loops of bowel all help with EAF prevention.[43] Once an EAF/ECF has formed, care is focused on nutritional optimization and wound healing.

Early initiation of EN improves outcomes for patients with EAF/ECF. EN, however, may result in increased fistula output and difficulty managing wound contamination and metabolic derangements (e.g., dehydration, electrolyte imbalances, and acid-base abnormalities). Contraindications to EN for patients with EAF/ECF include bowel discontinuity, ileus, and inability to tolerate EN due to metabolic and wound concerns. Patients who are unable to tolerate EN or are unable to meet nutritional goals with EN alone should be managed with parenteral nutrition. By optimizing nutrition, wound healing is maximized, and mortality rates are reduced.[44]

The mainstay of wound care for ECF/EAF is isolating the fistula effluent from the surrounding tissues to allow for wound healing and potentially spontaneous closure. Application of an ostomy appliance around the ECF is generally sufficient for ECF care. As opposed to ECF, wound management of EAF can be challenging due to lack of epithelialization around the wound. A combination of NPWT with commercially available devices (Wound Crown, 3M, Beirut, Lebanon) to isolate the EAF effluent allow for the formation of granulation tissue around the fistula and eventual reepithelialization or skin grafting, thereby converting an EAF into an ECF. If spontaneous fistula closure does not occur after nutritional support and wound care, nonoperative and operative interventions should be considered. Options for nonoperative closure include fibrin glue, endoscopic clipping, and extracellular matrix plug. These minimally invasive options result in successful fistula closure in 44% to 100% of patients, but data regarding these approaches remains scant.[45] Surgical intervention for persistent ECF should not be performed for at least 6 months and only once the wound has healed and the patient has fully recovered.

DELAYED ABDOMINAL WALL RECONSTRUCTION

Preparation for Abdominal Wall Reconstruction

The goal of definitive reconstruction is first to optimize the patient's condition and then to restore the structure and functional continuity of the musculofascial system to provide stable and durable wound coverage to minimize additional complications. Once the decision has been made to operate, preoperative risk factors must be carefully evaluated and optimized before an elective complex abdominal wall reconstruction is performed. Understanding preoperative risk factors during the process of patient and procedure selection is essential to minimize adverse postoperative occurrences.

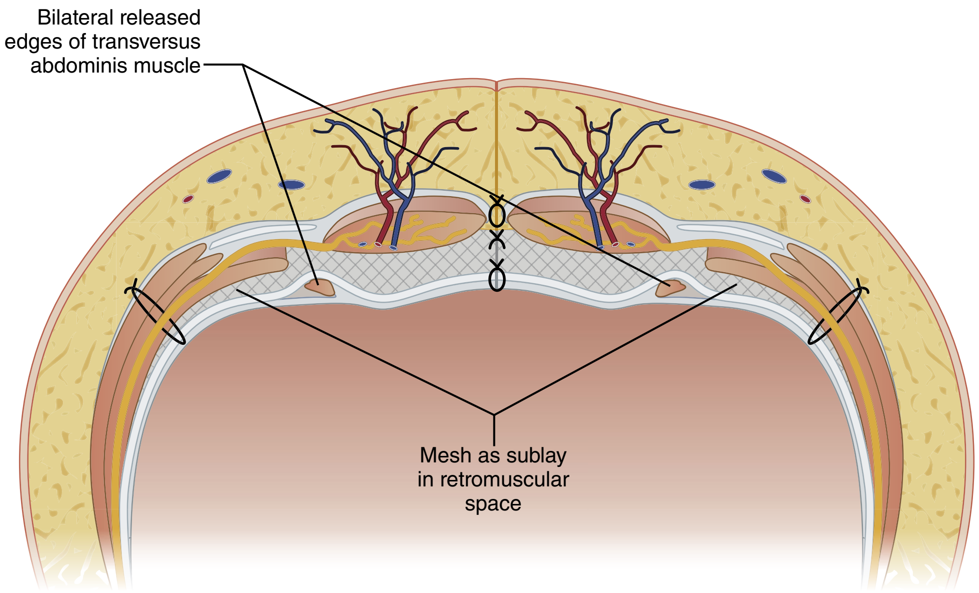
Minimizing risk in abdominal wall reconstruction surgery is a multidisciplinary effort aimed at tobacco cessation, clearing active infections, controlling diabetes, and normalizing BMI. Other risk factors associated with wound complications are less controllable and include enterotomy or stoma and previous ventral hernia repair. Every effort should be made to control diabetes by targeting a hemoglobin A1c less than 7, to maximize protein-calorie repletion, and to optimize cardiopulmonary status. Mandatory cigarette smoking cessation is required for at least 4 to 6 weeks before repair and urine cotinine screening can help document patient compliance. In patients with a previous methicillin-resistant *Staphylococcus aureus* infection, consideration should be given to decolonizing the patient or suppressing methicillin-resistant *S. aureus* carriers preoperatively and using vancomycin prophylaxis perioperatively.

Definitive Repair: Creating a Dynamic Abdominal Wall

Even with a great deal of preoperative planning, there is still no single approach that will solve all the needs for the reconstruction of a complex abdominal wall defect. It is essential that the surgeon review all prior operative reports and have a clear understanding of what remains in the wound and in what location. A preoperative CT scan of the abdominal wall is essential before any consideration of major reconstruction.

Various techniques for mobilization of the fascia medially with the component separation provide a tension-free repair of the rectus fascia and subsequent protection from infection from the overlying subcutaneous fat and skin. The classically described Ramirez technique for component separation requires large subcutaneous flaps to gain access to the lateral abdominal wall and release the external oblique fascia.[46] This technique has high wound morbidity and is, in general, not recommended for high-risk patients. Recently developed endoscopic methods to perform component separation release of the external oblique aponeurosis by using an endoscopic camera and avoiding division of the perforators have recently been described.[47]

The appreciation of abdominal wall function to create a dynamic abdominal wall unit has popularized two ideal reconstruction



Bilateral released edges of transversus abdominis muscle
Mesh as sublay in retromuscular space

FIGURE 37.9 Retrorectus positioning of mesh after Rives-Stoppa-Wantz repair.

techniques: the Rives-Stoppa-Wantz repair and the transversus abdominis release. Both use a retromuscular placement of mesh and are widely considered procedures of choice in abdominal wall reconstruction. Both techniques use a posterior component separation and the placement of lightweight macroporous synthetic mesh in the retrorectus space and outside of the peritoneal cavity. These techniques serve as optimal protection of the bowel from the mesh provided by the posterior rectus sheath, peritoneum, and omentum.

Rives-Stoppa-Wantz and Transversus Abdominis Release Techniques

In this technique, the posterior rectus sheath is incised approximately one-half of a centimeter from the fascial edge of the defect. The retrorectus plane is then developed to the lateral extent of the dissection, which is the linea semilunaris.[48] If this dissection is insufficient to close the posterior rectus fascia, an extension of this technique includes release of the transversus abdominis. In this technique, the transversus abdominis muscle is divided, which then allows entrance into the space between the transversalis fascia and the lateral edge of this divided transversus abdominis muscle. This allows the creation of a wide lateral dissection plane with substantial posterior and anterior fascial advancement. Both procedures avoid a major subcutaneous dissection and preserve the neurovascular bundle (Figs. 37.9 and 37.10).

Perioperative Considerations

Reconstruction of large abdominal defects can markedly change the physiology of respiration and alter the function of the diaphragm and respiratory musculature. Many surgeons have advocated the use of plateau pressure as an intraoperative method for gauging the effects of hernia repair on pulmonary function. Postoperative respiratory complications have been found to be significantly increased when the plateau pressure was raised above 6 mm Hg, and patients were nine times more likely to have complications with this finding.[49] Additionally, intraoperative and postoperative monitoring of abdominal pressures indirectly using bladder pressure measurements is routinely recommended when the abdominal wall defect is more than 600 cm^2.[49]

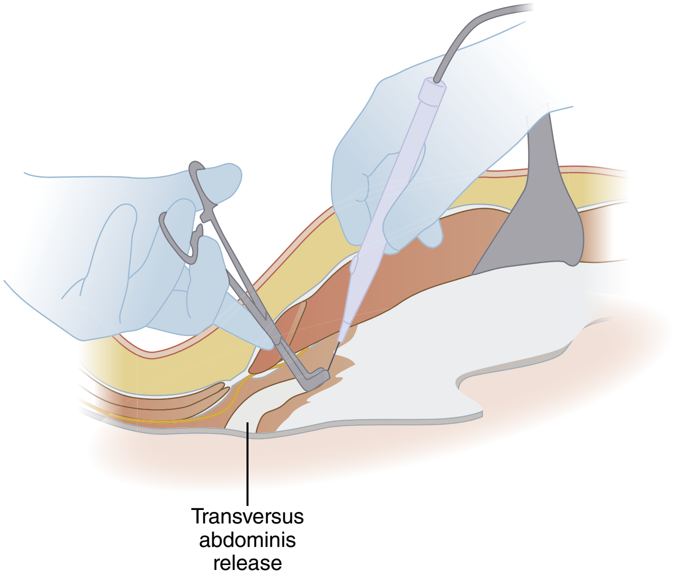


FIGURE 37.10 Transversus abdominis release.

Pain management is essential in this patient population, and the use of epidural catheters and transversus abdominis plane blocks substantially improves pain relief. These reduce narcotic use within the postoperative phase and decrease costs and postoperative morbidity. Both techniques increase early mobilization, thus reducing additional complications related to this extensive surgery. Long-acting injectable bupivacaine medication can provide prolonged relief of pain and reduce the use of narcotics.[50] Abdominal binders can also improve patient ambulation, pain control, and comfort.

Finally, a thorough understanding of the determinants of outcomes may be the most important factor in reducing complications and even death in this patient population. Nonoperative close observation strategies for asymptomatic large incisional hernias may be prudent in certain patient populations. Currently, there is no study evaluating patients with known incisional hernias who are managed nonoperatively.

SUMMARY

Patients with a difficult abdominal wall comprise a variety of etiologies and physiologic conditions. The now routine use of DCS for both trauma and emergency general surgery conditions results in an open abdomen, mandating surgeon knowledge of temporary closure techniques and also comfort with ICU optimization. After normalization of adverse physiology, abdominal reexploration is performed with either primary fascial closure or a plan for attempts at sequential closure of the abdomen. Efforts during these critical early postoperative days are paramount as inability to close the abdomen by 8 days is associated with a significant increase in complications, including EAFs. Coordinated efforts between surgeons and intensivists will ensure patients attain the best possible closure, whether this is eventual primary facial closure via multiple trips to the operating room, making the decision to place bridging biologic mesh to protect the abdominal viscera followed by subcutaneous tissue/skin closure or directed skin grafting, or the last option of a planned ventral hernia with subcutaneous tissue/skin repair closure. Careful monitoring of these patients for postoperative complications is paramount as they are common in this complex and critically ill patient population.

  Extremity Injuries
Complications

EPIDEMIOLOGY

Although trauma as a whole has been well characterized on local and international scales, the epidemiology of vascular injury specifically is relatively undefined. Epidemiology is dependent on accurate data, and there is a lack of large-scale data on vascular injury. This is because of the heterogeneity of the injuries, mechanisms, circumstances, and consequences of vascular injury.[1] The rate and impact of vascular injury are more well understood in individual populations. For example, in the most recent military engagements in Iraq and Afghanistan, the rate of vascular injury was as high as 12%.[2] Military vascular injuries tend to result more from extremity trauma, whereas civilians experience more torso wounds. The overall incidence is certainly lower in the civilian setting, yet exact numbers are hard to define. Iatrogenic trauma has also become a significant contributor, with endovascular techniques becoming standard practice in many instances. These have yet to be fully characterized. For the trauma and vascular surgeon, an understanding of the local factors contributing to the incidence and consequences of vascular trauma is vital to treatment and outcomes.

DIAGNOSIS

The prompt recognition and rapid and effective surgical management of vascular trauma remain challenging despite major advances in access to care produced by trauma systems development. The risk to life and limb remains significant, and the margin for error in both diagnosis and treatment of these injuries is very thin. Either delay in recognition of or failure in adequate management of vascular injuries remains alarmingly common in trauma centers. An organized approach with well-planned and implemented practice guidelines is essential to convert an error-prone process into one of timely diagnosis and safe and effective treatment.

Vascular injuries have a broad spectrum of clinical manifestations, varying from profound hemorrhagic shock to subtle findings, such as an asymptomatic bruit.[3] Because such a broad spectrum of clinical findings is associated with vascular trauma, it is best to assume that vascular injury is present until proven otherwise in all patients with hemorrhagic shock and all patients with extremity fractures.[3] Vascular injury can produce systemic symptoms of hypotension, tachycardia, and altered mental status due to hemorrhagic shock. As a result, vascular injury can be life threatening, and attention must initially be directed to the primary survey using the principles of Advanced Trauma Life Support (ATLS).[3] The airway must be assessed, adequate oxygenation and ventilation ensured, and intravenous access achieved. Once this is completed and resuscitation is under way, the secondary survey is undertaken. A thorough history and careful physical examination are then performed. This examination must include a careful inspection of the injured sites and wounds, a complete sensory and motor assessment, and a pulse examination of each extremity. The presence of a hematoma, bruit, or thrill must be noted.

The workup and diagnosis of vascular injuries should be based on three contiguous phases: physical examination, bedside diagnostic modalities, and targeted imaging or operative exploration. Initial history and physical examination are of the utmost importance, with specific attention to hemorrhagic or ischemic signs. Hemorrhagic signs, including an active external hemorrhage, large or expanding hematoma, pulsatile mass or palpable thrill, and hypotension or shock, indicate disruption of major blood vessels, arterial or venous, at the site of injury. Regardless of anatomic location, these signs should prompt expeditious attempts at hemorrhage control, requiring either further imaging localization or direct operative management.[4]

Hemorrhage management can be broken into five anatomic areas, each with specific considerations. In the head and neck, external hemorrhage is required for vascular injuries to result in shock. Relatively small and tightly organized tissue planes preclude significant internal hemorrhage. In the chest, each hemithorax can accommodate lethal amounts of hemorrhage from cardiac, pulmonary, or great vessel arterial and venous injuries. Abdominal and pelvic vascular injuries can also result in lethal hemorrhage, particularly from the aorta and iliac arteries. As in the head and neck, extremity vascular injuries generally cause hemorrhagic shock only if there is significant external hemorrhage. The patient with hypotension and a lack of chest, abdomen, and pelvic findings may have what appears to be a trivial neck or extremity laceration that initially communicated with a major vessel injury. A hemorrhage sufficient to produce hypotension can be followed by thrombosis. It is therefore necessary to obtain a history from the prehospital personnel about the amount of blood at the scene or the initial presence of severe wound hemorrhage. It is also necessary to thoroughly examine the patient for additional wounds and carefully assess each of them.[3]

Extremity vascular trauma may be immediately apparent on presentation because of external hemorrhage, hematoma, or obvious limb ischemia. A history of penetrating trauma associated with hypotension, pulsatile bleeding, or a large quantity of blood at the scene suggests vascular injury. Blunt trauma is also capable of causing significant vascular injury that can be overlooked when serious head, chest, or abdominal injuries are present. Extremity fractures may result in vascular injury. Supracondylar humerus fracture can be associated with brachial artery injury, and knee dislocation carries a significant risk of popliteal artery injury.[5] Crush injuries of the extremity without fracture may also result in vascular injury.

Some vascular injuries are manifested in a delayed fashion without initial findings. These consist of thrombosis of a previously partially disrupted but initially patent vessel, distal emboli from an intimal tear of the arterial wall with formation of platelet debris, and least commonly, rupture or expansion of a pseudoaneurysm that was initially small and contained by the outer arterial wall and local tissue. Ischemic signs, such as limb malperfusion, end-organ dysfunction, and various embolic phenomena, can be subtle or masked by various physiologic disturbances in trauma; therefore, careful evaluation is paramount. Ischemic signs manifest as loss of flow distal to the lesion, whether this be diminished or absent extremity pulses, neurologic or strokelike symptomatology, or abdominal pain and physiologic findings of hollow viscus and solid organ malperfusion. Although ischemic symptoms present distal to a suspected injury, it is not possible to fully localize or characterize these lesions based on history and physical examination alone. Further diagnostic modalities are therefore necessary in these instances to guide therapy.[4]

If distal pulses are diminished or absent, ankle or wrist systolic blood pressure should be determined with a continuous-wave Doppler device and compared with the uninjured side. A significant difference in systolic blood pressure (10 mm Hg) between extremities may be an indication of vascular injury. Doppler waveforms may also aid in determining presence of a vascular injury, with monophasic waveforms indicating limited proximal flow. If anything other than strong biphasic or triphasic waveforms is obtained, the contralateral limb should also be evaluated in comparison. Doppler may also be used to calculate an Injured Extremity Index (IEI), the ratio of systolic blood pressure in the injury limb to that in the unaffected limb. Any IEI less than 1.0 is considered abnormal and representative of limited arterial flow in the injured extremity.

In addition to Doppler, focused assessment with sonography in trauma (FAST) should be routinely performed to evaluate for free intraabdominal, pelvic, pericardial, and thoracic fluid indicative of hemorrhage. Although nonspecific, findings on this examination may help guide further management of hemorrhage.

X-ray is another imaging modality that can be quickly performed at bedside to guide evaluation of vascular injury. Although vascular injuries cannot be directly imaged with radiographs, both plain chest and pelvic radiographs may contain findings suggestive of major vascular injury, such as massive hemothorax or an unstable pelvic fracture.

It is well established that patients with "hard" findings of vascular injury (Table 38.1) should be taken directly to the operating room. However, in patients with "soft" findings (see Table 38.1), vascular imaging can be used to rule out the need for operation. In addition, patients with hard findings but with multilevel injuries in the same extremity may also need imaging. Catheter arteriography is both sensitive and specific in the diagnosis of extremity vascular injuries. However, computed tomography angiography (CTA) with the latest generation scanners is readily available and highly accurate and obviates the delay caused by mobilizing the angiography suite for catheter angiography.[6] Although this imaging technique requires an infusion of contrast material, it does not require arterial catheterization, is easily performed, and is less costly and less time consuming than conventional angiography.[6] In patients with suspected vascular injury, CTA has become the standard imaging modality for diagnosis and intervention planning. CT has the added benefit of evaluating surrounding soft tissue and bony injury, which may aid in surgical planning or

- History of moderate hemorrhage
- Proximity fracture, dislocation, or penetrating wound
- Diminished but palpable pulse
- Level of peripheral nerve deficit in proximity to major vessel

prognostication. A downside to CT, which can often be seen in firearm trauma, is the presence of imaging artifact (Fig. 38.1) resulting from the presence of metallic fragments (e.g., bullets, pellets, shrapnel).[7]

Although CT and CTA imaging modalities have become commonplace in the modern trauma patient's workup, formal angiography remains the gold standard for evaluation of vascular luminal characteristics. It is able to provide dynamic information regarding flow characteristics within the injured vessel and has the potential to aid both diagnosis and treatment (if amenable to endovascular repair). This modality, however, requires specialized equipment and training that may not be readily available at some trauma centers.[8]

Severely injured patients who must be taken to the operating room for treatment of life-threatening associated injuries, such as penetrating thoracic injury or ruptured spleen, may not be able to undergo CTA. In such cases, it is not prudent to delay operative therapy to obtain formal vascular imaging. An on-table arteriogram can be obtained in the operating room by cannulating the artery proximal to the suspected vascular injury, injecting 20 to 25 mL of a full-strength radiographic contrast agent, and taking a radiograph or using fluoroscopy. This may be helpful in both initial diagnosis of injury and subsequent evaluation of a vascular repair or bypass before leaving the operating room.

If doubt remains about the presence of a vascular injury and the imaging studies and other diagnostic tests are inconclusive, there is a role for operative exploration and direct assessment of the artery. Routine operative exploration in the stable patient with soft signs, however, has a 5% to 30% incidence of morbidity, occasional mortality, and low diagnostic yield.[9] These patients are better served with formal vascular imaging.

Duplex color flow imaging is not used for the acute assessment of vascular injury. Wounds, swelling, air in the tissue, and dressings or splints impair the ability to obtain satisfactory images. Duplex imaging does have a role in the follow-up of treated lesions (e.g., to assess patency of bypass grafts or to detect luminal stenosis at an anastomosis) and in the follow-up of nonoperative management of minimal vascular injury, such as small pseudoaneurysms or arteriovenous fistulas.

PRINCIPLES OF OPEN MANAGEMENT

Preparation for Operative Management

Operative procedures to manage vascular injuries should be limited to those surgeons who are capable, experienced, and qualified. Board certification in vascular surgery is not enough to qualify a surgeon as capable of handling these injuries, just as the lack of certification does not necessarily disqualify a surgeon. Many surgeons who perform elective vascular surgery are not sufficiently experienced in the management of vascular trauma. Conversely, there are many trauma surgeons who are very skilled in vascular technique by virtue of their interest and experience. The results of major open vascular repairs are dependent on the skill level of the vascular trauma–capable surgeon, independent of board preparation. In a multicenter review of close to 700 major extremity vascular injuries, board-certified general surgeons and board-certified vascular surgeons had nearly identical high limb salvage rates for major vascular surgical repairs.[10] Every trauma center needs to develop a call panel of surgeons with the skill and knowledge to perform the full spectrum of vascular trauma repairs.

Successful operative management of vascular injuries requires a systematic approach with careful preparation. This begins with airway control, adequate intravenous access, and availability of blood products. The administration of these blood products, however, should not begin before obtaining control of hemorrhage unless the patient is profoundly hypotensive.[3] If the blood pressure is below 80 to 90 mm Hg, the goal should be to provide adequate volume restoration with whole blood or balanced resuscitation (1:1:1) to support transport to the operating room for definitive hemorrhage control without delay. Volume infusion that raises the blood pressure above a systolic pressure of 90 to 100 mm Hg may increase bleeding and have a negative impact on outcome, particularly if the infusion delays transport to the operating room.[3]

The most commonly omitted step in preparation is a failure to document preoperative extremity neurologic status. The presence of a neurologic deficit after operative vascular repair without knowing the preoperative status presents a difficult management

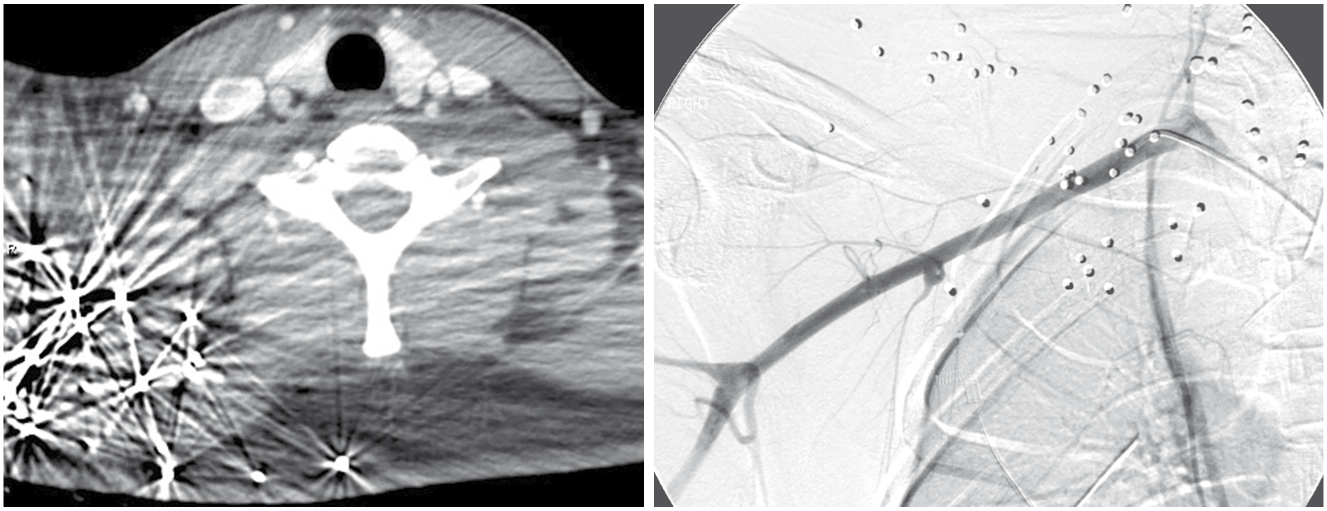

FIGURE 38.1 CT with contrast imaging of gunshot wound to the right shoulder. Metallic scatter obscures adequate visualization of the arterial structures to exclude injury. The image on the *right* shows the subsequent traditional angiogram, which afforded multiplanar views that subsequently confirmed the absence of arterial injury.

challenge. A new neurologic deficit after vascular repair merits investigation and, possibly, reoperation. Therefore, a thorough preoperative neurologic examination and careful documentation are essential to effective management.

After the decision is made to proceed with open management, the operating room and staff should be properly prepared for potential needs within the case. Ideally, a radiolucent operating table should be used in anticipation of performing an on-table angiogram if needed. The patient should be positioned supine with arms abducted and should have skin preparation in usual trauma fashion from chin to midthighs and to the table bilaterally. Depending on the site of suspected vascular injury, the upper or lower extremities should be prepped circumferentially to aid in vascular exposure or allow for harvest of greater saphenous vein for use as a graft. If an upper extremity peripheral vascular injury is suspected, an arm board should also be added to aid in positioning and exposure.[4]

Broad-spectrum preoperative antibiotics (and tetanus toxoid, if it is a penetrating wound) should be administered, and if there is an isolated extremity injury without other significant systemic sources of hemorrhage, a bolus of 100 to 150 units/kg of heparin or a fixed dose of 5000 units may also be given intravenously. Systemic heparinization should be avoided in patients with torso injuries, head injuries, or multiple extremity injuries.[11] Although this is common in elective vascular surgery, systemic heparinization is debated in trauma. A safe alternative to this may be to regionally instill heparinized saline at the site of repair to prevent thrombosis.[11] Ultimately, its use should be determined by the operative surgical team.

The operative management of extremity vascular injuries must be carefully orchestrated with the overall care of the patient. The choice between definitive repair and damage control should be made as soon as possible in patients with life-threatening torso injuries or severe head injuries. This includes coordinating two surgical teams, if possible, to work simultaneously to care for the torso injury and the extremity vascular injury at the same time. Associated injuries to the soft tissue and bone require a coordinated assessment and treatment with orthopedic and plastic surgery consultants. These specialists should be involved as early as possible to facilitate any additional imaging or diagnostic procedures before proceeding to the operating room. The conduct of the operation should also be discussed with these colleagues. For example, the use of damage control procedures with shunt placement, followed by orthopedic stabilization, can remove the sense of urgency to definitively repair the vasculature. Extensive soft tissue injuries may compromise the proper coverage of vascular repairs and fracture fixation. The advice and assistance of a plastic and reconstructive surgeon can be helpful in obtaining coverage of exposed grafts and fractures.

Vascular Exposure and Control

Proximal control is the first priority in the exposure of vascular injuries. In the torso, chest injuries with life-threatening hemorrhage are best approached through a fourth intercostal space left anterolateral thoracotomy that can be extended across the sternum into the third intercostal space of the right side of the chest to create a "clamshell" incision. Thoracic outlet and proximal neck vascular injuries may require median sternotomy with extension above the clavicle up along the ipsilateral sternocleidomastoid muscle.

Retrograde endovascular balloon occlusion of the aorta (REBOA) with the 7-French (Fr) catheter via common femoral access should be considered for patients with suspected abdominal or pelvic injury (Fig. 38.2).[12] In unstable patients, it can be advanced to the descending aorta in the chest and inflated. In stable patients in whom difficulty with proximal control is

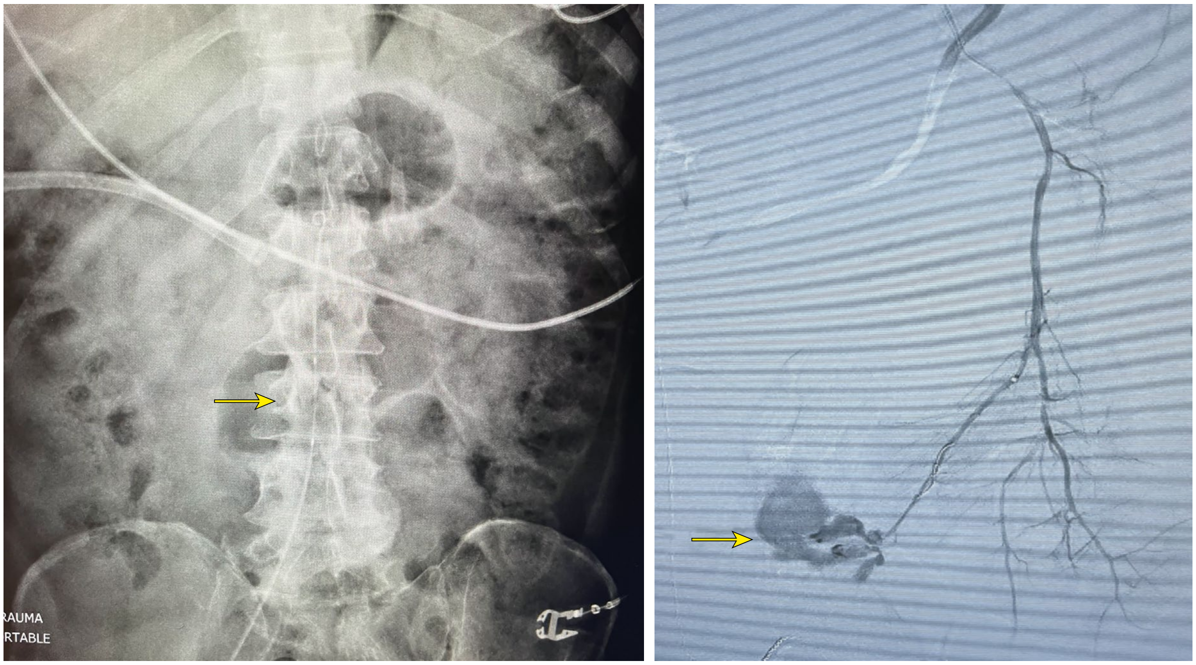

FIGURE 38.2 Plain film on the *left* demonstrates positioning of a resuscitative endovascular occlusion of the aorta balloon *(arrow)* placed in the emergency department for a hypotensive patient with pelvic hemorrhage not responding to a binder and transfusion. The patient was subsequently taken emergently to the hybrid suite for embolization of significant hemorrhage from his left internal iliac artery *(right image and arrow)*.

anticipated, it can be similarly positioned but left uninflated. For abdominal vascular injury, a generous xiphoid-to-pubis incision is needed for adequate exposure.[13] Proximal control for abdominal aortic injuries should be obtained just below the aortic hiatus of the diaphragm or may require a left anterolateral thoracotomy to clamp the distal thoracic aorta. If REBOA or intrathoracic aortic clamping is used, it should be converted to a clamp low on the aorta while providing proximal control as possible to allow visceral artery perfusion to prevent ischemic injury.

In proximal extremity injuries with active hemorrhage, the first incision site is chosen to give the fastest exposure of inflow vessels for clamping. For proximal upper extremity injuries, this may include incisions over the infraclavicular region of the chest to expose the axillary artery. For injuries in the groin, prepare to enter the lower quadrant of the abdomen for access to the external iliac vessels. In mid- and distal extremity vascular injuries associated with active hemorrhage, tourniquets can rapidly obtain control in the trauma resuscitation room. In the operating room, have one team member precisely compress the bleeding site with a gloved hand and a sponge, remove the tourniquet, and prepare the extremity. A heparin bolus is then given, if appropriate, the extremity is prepared and draped, and a sterile tourniquet is placed proximal to the wound and inflated. The injury site can then be explored in a controlled fashion, with clamps or vessel loops placed above and below the vascular injury. In certain injuries, distal arterial occlusion and retrograde intraluminal insertion of a Fogarty catheter with a stopcock to maintain balloon inflation will provide rapid hemorrhage control.[5]

Incisions used to manage vascular injuries are often the same as those used to manage elective cases but are generally more generous. The use of smaller incisions may lead to errors in identifying the extent of vascular injury, adequately controlling branch vessel hemorrhage, and identifying associated venous lacerations. This is particularly true for popliteal artery and vein injuries. A limited approach with separate medial above- and below-knee incisions will not adequately expose the site of injury. Similarly, the posterior approach with the patient prone is not recommended because of the difficulty in obtaining adequate proximal and distal exposure for both vascular repair and bleeding control of associated venous injuries. A medial incision from the proximal popliteal space to the distal popliteal space with division of the medial head of the gastrocnemius muscle and the semimembranosus and semitendinosus muscles with full exposure of the popliteal artery and vein and the tibial nerve provides adequate exposure. This ensures adequate vascular control and the opportunity for successful repair. Closure of the wound to include approximation of the divided muscles yields an excellent functional result. Dividing the inguinal ligament in the groin, dividing the pectoralis major in the axilla, and removing the midclavicle may rarely be necessary. In each of these areas, rapid endovascular balloon occlusion offers an excellent adjunct to proximal control. In the presence of life-threatening hemorrhage that cannot be controlled by any other approach, these structures should not stand in the way of adequate exposure and control.

Once both proximal and distal control of the vessel has been achieved, careful dissection can then be carried out to identify the site of injury. The injury can typically be found within a hematoma extending into surrounding soft tissue. Once the injury is identified and characterized, the decision is made regarding definitive repair or damage control with a temporary shunt. This is mainly based on the patient's physiology. Unstable patients should undergo damage control management, whereas stable patients may proceed with definitive repair. Damage control of vascular injuries is discussed in a later section.

Choice of Repair and Vascular Conduits

In preparation for definitive repair, the injured vessel should be debrided back to healthy tissue in all layers, including intima, media, and adventitia. This may require resection of a large portion of vessel; however, this is vital to ensure a healthy repair without further complications such as pseudoaneurysm, thrombosis, or intimal dissection flap. The options for definitive repair of vascular injury include primary closure, patch angioplasty, primary end-to-end anastomosis, or repair with interposition graft. The choice of repair is dictated by the injury type identified. Primary repair of an artery or vein can include direct suturing of a vessel wall injury or an end-to-end repair of two vessel segments that are less than 2 cm apart. The lack of anastomoses and prosthetic material is advantageous; however, there is a risk of dehiscence if under too much tension or luminal narrowing or stenosis.[11]

Vessel injuries that cannot be repaired by primary repair or end-to-end anastomosis will require an interposition graft. The most desirable graft is autologous great saphenous vein harvested from an uninjured leg.[5] Native vein graft is preferable because it has elastic properties that make it compliant with the normal pulsatile flow of an artery; it has a diameter that approximates that of an extremity artery, producing an adequate size match for grafting in the arm and leg; it is not thrombogenic; and it has superior long-term patency in elective vascular surgery compared with prosthetic material when it is used with smaller vessels (popliteal and tibial). The cephalic vein and lesser saphenous vein have been suggested as suitable second choices, but the cephalic vein is less muscular than the greater saphenous and, like the lesser saphenous, may present problems with harvesting in a trauma patient.[5] Also, upper extremity venous access becomes compromised when the cephalic vein is used. It is imperative to remember, however, that venous valves may impair or fully occlude flow if not attended to properly. Therefore, the vein should be implanted in reverse orientation, or if this is not possible, a valvulotomy may be performed. Venous side branches should also be ligated to prevent extravasation from the repair and should be done in a fashion that avoids venous stenosis or kinking.[14]

The saphenous vein may not be suitable in all instances because of inadequate size or because it has been traumatized or harvested previously. In such cases, a prosthetic conduit may be needed. Initial experiences with the use of prosthetic material (e.g., Dacron) in traumatic vascular injuries were not good. Rich and Hughes reported a complication rate of 77% (infection and thrombosis were the most common) in 26 patients.[15] However, more recent experience with newer graft material (polytetrafluoroethylene [PTFE]) has shown improved patency (70%–90% short term) and rare infection (even in contaminated wounds).[16] Early rates of patency with PTFE grafts are equivalent to those with vein for injuries proximal to the popliteal artery and in the brachial artery. Distal to these levels, PTFE is inferior to vein for popliteal and more distal vessels and in the arm and leg. PTFE grafts of less than 6 mm should not be used.[16] PTFE and vein grafts must be covered, or there is a significant risk of hemorrhage from desiccation of the vein, with subsequent autolysis or breakdown of the anastomosis.[12,16]

Intraoperative Imaging and Noninvasive Evaluation

The successful management of vascular injury requires precisely knowing the status of blood flow in the area of the vessel injury.

Preoperative imaging with catheter angiography or CTA is not always possible. In addition, when a vascular repair has been completed, the presence of thrombus, kinking, or unexpected technical problems may cause early failure. Intraoperative imaging is therefore an important part of assessing the injured vessels and the repair site.[5] Either single-injection radiography or fluoroscopy is effective in providing images in the operating room. Intraoperative duplex scanning is also effective but requires significant training and experience for it to be performed adequately. Handheld continuous-wave Doppler interrogation can be helpful but requires considerable experience to be used effectively. Measurements of ankle or wrist pressure may be misleading because of regional vasospasm in the proximal injured extremity, resulting in a reduced distal pressure compared with the uninjured leg. Intraoperative radiographic imaging remains the most accurate and useful method to detect technical problems with a vascular repair or determine the presence of thrombus in the runoff vessels distal to a repair. Routine completion arteriography after vascular repairs will yield findings of clinical importance in approximately 10% of patients.[5] All postrepair assessments should be accurately documented and communicated among the care team. The first 24 to 48 hours after a vascular repair are the most critical for identifying potential complications, and patients should ideally be admitted to an intensive care unit (ICU) for frequent hourly neurovascular monitoring.[17]

Role of Tissue Coverage

All vascular repairs must be covered to prevent desiccation and disruption. In crushed or badly mangled extremities, this can be a difficult challenge. Rotation of regional muscle or skin flaps may be required. The early involvement of a plastic and reconstructive surgeon is essential to obtain tissue coverage when there is extensive soft tissue injury or loss. Local muscle can be advanced into the wound at the initial operation. If there is a large, contaminated wound and local muscle viability is questionable, early reexploration and preparation for a free flap should be considered. On occasion, tissue loss may be so extensive that an extraanatomic course for an interposition graft may be required. Attention to coverage is also essential in damage control procedures to avoid shunt dislodgment during dressing changes.

Common Errors and Pitfalls

The management of vascular injuries is challenging. An organized approach is necessary to avoid the common errors and pitfalls. One of the most common errors is the lack of recognition of an extremity vascular injury in a patient with multiple torso injuries. Failure to recognize and adequately treat compartment syndrome is another error that is all too common and has devastating consequences. In torso injuries to the great vessels, failure to adequately expose and control the injured site can lead to a rapid death from exsanguination. Finally, failure to recognize the need for damage control techniques and a rapid completion of the operation in an unstable patient can also be deadly. The condition of the patient determines the timing of definitive vascular repair after damage control. Hemorrhage must be controlled, coagulopathy and acidosis corrected, and temperature normalized. An organized approach to the trauma patient mitigates errors.

PRINCIPLES OF ENDOVASCULAR MANAGEMENT

Minimal Vascular Injury and Nonoperative Management

The widespread application of CTA in the evaluation of injured vessels results in the detection of clinically insignificant lesions.[18] There is now an extensive body of experience with lesions that are not limb or life threatening. These minimal vascular injuries include intimal irregularity, small nonocclusive intimal flaps, focal spasm with minimal narrowing, and small pseudoaneurysms. They are often asymptomatic and usually do not progress.[5,18]

A small, nonocclusive intimal flap is the most commonly encountered clinically insignificant minimal vascular injury. The likelihood that it will progress to cause either occlusion or distal embolization is approximately 10% or less.[5,18] This progression, if it occurs, will be early in the postinjury course. Spasm is another common minimal vascular injury. This finding should resolve promptly after initial discovery. Failure of the return of normal extremity perfusion pressure indicates that a more serious vascular injury is present, and intervention is needed. Small pseudoaneurysms are more likely to progress to the point of needing repair and must be actively observed with duplex color flow imaging. Arteriovenous fistulas always enlarge over time and should be promptly repaired.

There is extensive evidence supporting nonoperative therapy for many asymptomatic lesions. However, successful nonoperative therapy requires continuous surveillance for subsequent progression, occlusion, or hemorrhage. Operative therapy is required for thrombosis, symptoms of chronic ischemia, and failure of small pseudoaneurysms to resolve.[18]

Endovascular Management

Endovascular repair of vascular injuries is increasingly common.[19,20] This approach has become particularly effective in stable large-vessel injuries and in areas difficult to expose for direct repair. However, despite advances in endovascular techniques and devices, this approach has not supplanted open surgery in the management of most peripheral vascular injuries. Endovascular therapy for atherosclerotic arterial disease has become the first choice in management. Endoluminal stent deployment for occlusive lesions and stent graft for aortic aneurysms have become widely accepted. However, there is a strong tendency to generalize from this elective experience in elderly patients with atherosclerosis to the treatment of younger patients with acute vascular injuries. The evidence to support these approaches in preference to traditional open techniques in peripheral arterial injuries is yet to be demonstrated, and there have been problems.[5,20] The striking decrease in open vascular surgical experience among general surgeons and vascular surgeons trained in the 21st century creates a lack of comfort and competence in performing open vascular repairs.[21] A balanced approach using each of these techniques where they best apply, supported by clinical evidence, is essential to good outcomes in patients with vascular trauma.

Endovascular Operating Rooms

There is a widespread proliferation of “hybrid” operating rooms. These high-technology suites have both advanced imaging capability and traditional operating room properties. They require a major commitment of resources and personnel to be effective. They are ideal for complex elective endovascular cases. Not all trauma centers have hybrid operating rooms, or if they do, they may not be able to staff them on an emergency basis for the often-after-hours management of vascular trauma.

Many centers do, however, have highly functional hybrid rooms with high-resolution digital subtraction C-arm fluoroscopy equipment, mobile cabinets with the appropriate catheters and stent grafts, and on-call technical staff. They can create hybrid suite capabilities in an operating room large enough for the C-arm and the rolling cabinets with a standard orthopedic surgery operating table that accommodates fluoroscopy. An unstable trauma patient taken directly to the operating room with a major vascular injury or solid organ hemorrhage can be placed on a radiolucent surgery table and then be managed with all the functionality of a dedicated hybrid operating room. Many trauma centers already provide these mobile capabilities to their vascular surgeons performing elective endovascular abdominal aortic aneurysm repair. All trauma centers need to develop this capacity for their trauma patients. Rooms such as these allow for the expedient treatment of the subset of trauma patients who may require and benefit from simultaneous endovascular and open surgical interventions.

Vascular Access

Once the choice for endovascular approach is made, arterial and/or venous access options must be considered. After open cutdown, nearly any adequately sized vessel may be cannulated, including the common carotid, iliac, and aorta, if necessary. Percutaneous access may also be achieved at numerous sites, including venous access at the basilic, cephalic, subclavian, internal jugular, saphenous, popliteal, and common femoral veins and arterial access at the common femoral, popliteal, radial, brachial, axillary, and pedal arteries. When considering access site, one must consider the feasibility of endovascular methods from this site, the ability to maintain hemostasis after sheath removal or convert to open cutdown if necessary, and what downstream tissue may be affected by either partial or complete flow occlusion during sheath placement.[22]

Although numerous access sites exist, the majority of percutaneous interventions may be achieved through retrograde access to the common femoral artery.[22] This site should ideally be accessed below the inguinal ligament, demarcated by the line between the anterior-superior iliac spine and the pubic tubercle, to decrease the risk of retroperitoneal hemorrhage. Access may be obtained through palpation and use of anatomic landmarks alone; however, ultrasound guidance greatly facilitates safe and successful cannulation if available. Ideally, a standard 18-G or micropuncture 21-G access needle should be passed through a noncalcified portion of the common femoral artery overlying the femoral head, to allow for compression for hemostasis, and 1 cm proximal to the bifurcation into the superficial femoral and profunda arteries. Once percutaneous access is achieved, a guidewire may be advanced through the access needle, and the needle may be then exchanged for a sheath. The sheath should then be flushed with heparinized saline, and placement should be confirmed with fluoroscopy.

Upon completion of the endovascular procedure, hemostasis should be achieved after removal of the sheath to prevent hematoma or pseudoaneurysm formation. Sheaths up to 7 Fr may be safely removed with only manual pressure to the access site. Commonly, pressure is held immediately proximal to the puncture site for 3 minutes per French size in sheath diameter (e.g., 21 minutes for a 7-Fr sheath). Additionally, various percutaneous arteriotomy closure devices are currently available on today's market. Broadly, these devices either place an extravascular plug onto the artery or place a percutaneous suture through the arteriotomy for closure.[22] Both types of closure devices should be managed only by those trained to do so because misuse carries the risk of complications such as arterial thrombosis, distal emboli, dissection, hemorrhage, and infection.

Endovascular Management of Torso Vascular Injuries

Endovascular techniques offer a variety of options for hemorrhage control in the torso. Intraarterial catheter-directed embolization has become a mainstay of the management of solid organ hemorrhage in the abdomen. Whether it is used as the sole treatment or in combination with open procedures, this approach has been effective in liver, spleen, and kidney injuries. Less commonly used intraarterial balloon occlusion for proximal control is a promising adjunct to open repair.[12,23] The availability of REBOA is growing, and in many institutions, it has become common practice in the same clinical setting of exsanguinating abdominal hemorrhage in which an aortic cross-clamp in the chest is needed. In trauma centers with appropriately trained surgeons and proper equipment, these techniques are quick, accurate, and easily performed. The reluctance to adopt new and promising technology must be avoided, and trauma surgeons need to either add surgeons or radiologists with endovascular capabilities to their specialty physician call panels or obtain the training themselves.

The early use of catheter-directed control of hemorrhage associated with pelvic fracture is an effective method of limiting blood loss and improving outcome.[24] This approach is well tolerated and has proved superior to open attempts at hemorrhage control by packing in most patients. Unstable patients benefit from an immediate trip to the operating room. If intraoperative endovascular capability is present, a combined approach may offer the best results.

Endovascular stent graft placement for the management of select great vessel injuries has become the procedure of choice (Fig. 38.3).[25,26] New devices with better proximal fixation seem to be preventing many of the early catastrophic graft failures of older devices. A comparison of the relative degree of risk of endovascular techniques to open repair reveals why this newer approach has gained widespread application.[26,27] Lifelong CT imaging is necessary because of the possibility of delayed endoleak and the possible loss of device fixation as the aorta enlarges over time. There is a definite role for covered stents in proximal branches of the aorta in both the thorax and abdomen. In stable injuries at risk for delayed hemorrhage or thrombosis, carefully placed stents have the potential to lower morbidity compared with open procedures that require extensive operative dissection for exposure and control. Endoluminal management with stent grafts appears most effective in those torso injuries that are surgically inaccessible with the potential for significant hemorrhage in stable patients. These techniques should be used only in centers with an active elective endovascular practice that has experience in treating trauma patients.

Endovascular Management of Cerebrovascular Vascular Injuries

Endovascular techniques offer advantages in anatomic regions where direct operative control is difficult or impossible. For example, hemorrhage from a penetrating injury at the base of the skull is extremely difficult to control. Catheter-directed placement of coils, balloons, or hemostatic agents in the injured carotid or vertebral artery could be lifesaving. The use of balloon occlusion to achieve proximal control may negate the need for a larger operation with increased morbidity, such as a sternotomy for zone I neck injuries. Care must be taken, however, to choose the correct balloon size for occlusion, given the risk of rupture.

Embolization is another tool that may be safely and selectively used in cerebrovascular injury (Fig. 38.4). The external carotid and its branches may be safely embolized, and embolization has

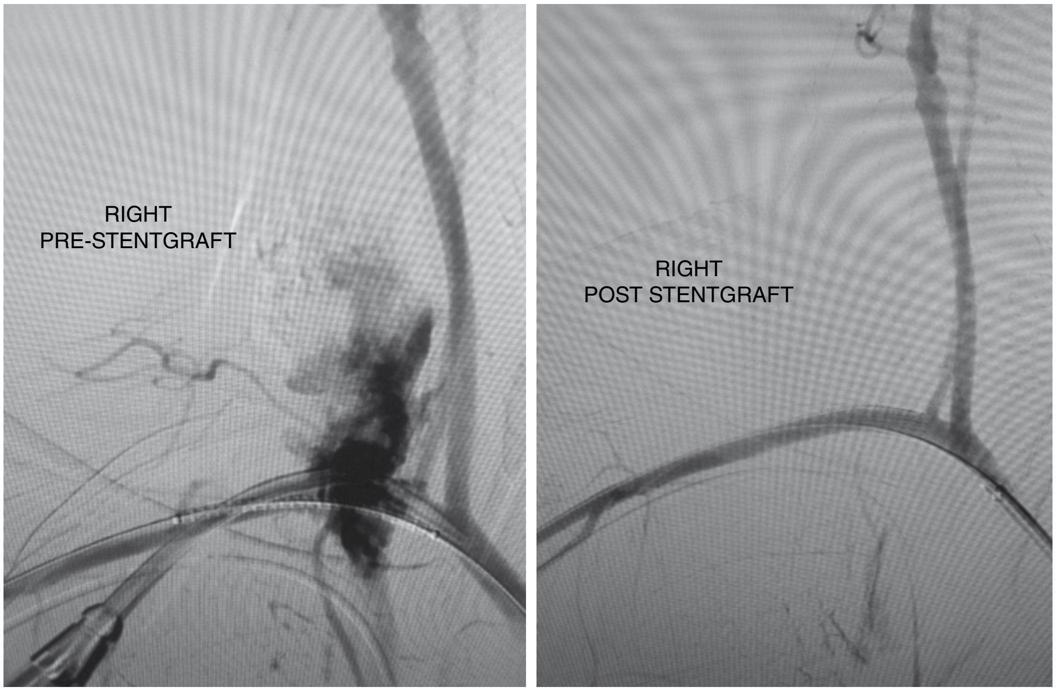

FIGURE 38.3 Right subclavian artery injury with demonstrated active extravasation on angiogram *(left panel)*. Subsequent endovascular stent graft deployment and repair of the injury with completion angiogram *(right panel)*.

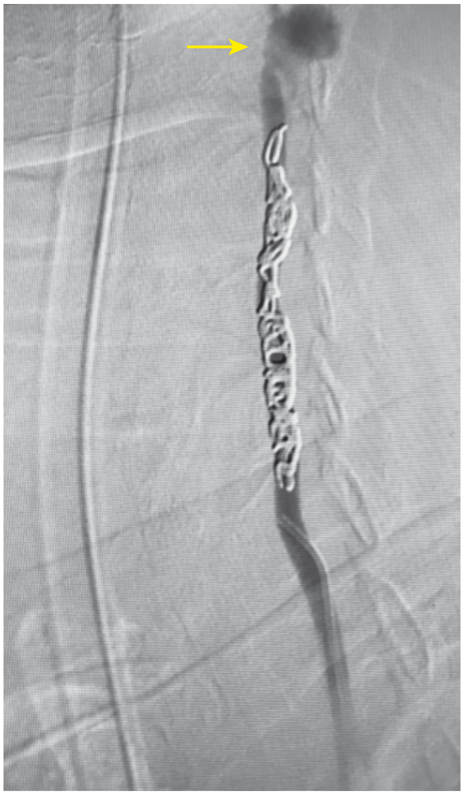

FIGURE 38.4 Penetrating vertebral artery injury managed with coil embolization. *Yellow arrow* points to point of injury with extravasation of contrast.

become the preferred management in stable patients with isolated injuries. Proximal embolization of a nondominant vertebral artery may also be used in select patients, with good outcomes.[4]

Stent placement initially appeared less effective than anticoagulation in partially occluded injuries without associated hemorrhage.[28] However, the role of stents in cerebrovascular trauma continues to evolve, and stents may prove to be safe.[29,30] For internal carotid artery injuries in zone III, which are technically difficult to access through an open approach, bare-metal stents have become a safe and useful management strategy. This use of endoluminal cerebrovascular interventions requires significant expertise and experience. If such experience does not exist at the receiving hospital, consideration should be given to transferring the patient to a medical center with experience in this mode of therapy.

Endovascular Management of Extremity Vascular Injuries

The use of stent grafts in extremity vascular injuries is becoming more common.[19,20] The long-term results, however, have not been documented, and caution should be used in considering this type of treatment. In hemodynamically stable patients with contained hemorrhage, difficult-to-access proximal subclavian or iliac arterial injuries may be effectively treated with covered stents. In the extremities distal to these areas, autologous vein interposition grafts have excellent long-term patency rates and remain the gold standard for vascular repairs.

The loss of open vascular surgery experience in general surgery residencies and vascular fellowships has resulted in many trauma and vascular surgeons resorting to endovascular repair in the extremities. This trend is particularly dangerous in the popliteal artery, where there is a high risk of stent or endograft thrombosis and subsequent limb-threatening ischemia. Early patency of endovascular repairs can be, unfortunately, followed by delayed thrombosis, with an extremely high rate of severe distal ischemia. Open repair with suitable saphenous vein interposition graft placement is the best approach, and the results of all other techniques need to be compared with this traditional standard treatment.

Catheter-directed therapies for controlling hemorrhage from large branch vessels in the extremities are often effective and sufficient to manage these injuries. Endoluminal treatment is used sparingly for pseudoaneurysms of extremity arteries. Small pseudoaneurysms are likely to resolve without any intervention, and large pseudoaneurysms are best treated with open techniques because the risk of arterial thrombosis or distal embolization is high with this endovascular intervention.

Who Should Perform Endovascular Repairs?

Successful management of vascular injuries requires that the most qualified person do the indicated intervention in the appropriate patient in the appropriate place at the appropriate time. Endovascular surgery is an operative procedure and, like all operations, should be performed by readily available trained clinicians who not only are cognizant of the technical aspects of a procedure but also are knowledgeable about the disease for which the procedure is being performed. In many centers, this person is the interventional radiologist. Other centers have catheter-trained vascular surgeons, and a few others have trauma surgeons who are capable of performing endovascular procedures. Catheter skills training is being integrated into many surgical critical care fellowships and may subsequently become more available in the near future at many trauma centers.

Endoluminal management of vascular trauma does not require a full endovascular hybrid operating room, as explained before. Planning and preparation, however, are essential for the endovascular capability, which, more often than not, is needed in the middle of the night. Preparing a team that can perform these techniques and can organize the appropriate equipment with brief notice requires commitment, dedication, collaboration, and training.

PRINCIPLES OF DAMAGE CONTROL

Vascular Damage Control

Damage control has gained wide acceptance in trauma surgery and is directed at rapid control of hemorrhage and closure of enteric wounds so that the patient can be warmed and resuscitated. The choice between definitive, time-consuming vascular repair and temporary measures that achieve control must be made early in care of patients with vascular injury and hypovolemic shock. This is particularly important when an extremity vascular injury is associated with major torso injuries. Damage control strategies in vascular surgery focus on rapid hemorrhage control and restoration of end-organ perfusion. Hemorrhage control mainstays include tourniquet and ligation and, in extreme instances, amputation. Temporary restoration of blood flow is accomplished using intraluminal shunts, with the addition of fasciotomy as needed. Intraaortic balloon tamponade with REBOA has also emerged as a temporary method of hemorrhage control while simultaneously improving end-organ perfusion.

Hemorrhage Control

Field tourniquet use was repopularized during recent US military conflicts and was a large success.[31] The associated morbidity in combat was overall low, with a 1.5% incidence of nerve palsy, 0.4% risk of amputation, and approximately 30% rate of fasciotomy in those left for greater than 2 hours.[32] Similarly, tourniquet use in civilian practice has been found to be effective for prehospital control of extremity hemorrhage and has been associated with improved survival.[24]

Ligation should be reserved for vessels with adequate distal collateral flow in patients who are too unstable for definitive repair. In the torso, this includes the subclavian and innominate arteries, the celiac artery, and the inferior mesenteric artery. In the upper extremity, proximal injuries of the axillary artery and distal injuries to either the radial or ulnar artery may be ligated, provided there is evidence of adequate distal collateral flow assessed by either physical examination or continuous-wave Doppler interrogation. In the groin, profunda femoris artery injuries can be ligated if the common and superficial femoral arteries (SFAs) are intact. Similarly, in the lower extremity, ligation of a single tibial artery or the peroneal artery can be performed after a similar assessment. If distal perfusion is compromised, an intraluminal shunt should be inserted rather than ligating the vessel. Superior mesenteric artery (SMA) ligation is associated with a high risk of bowel necrosis, and damage control is best accomplished with placement of an intraluminal shunt. In the extremities, ligation of the brachial, external iliac, superficial femoral, or popliteal artery has a high likelihood of producing limb-threatening ischemia and should be avoided, if possible.

Temporary Restoration of Blood Flow

A variety of commercially available shunts can be used for damage control (Fig. 38.5). If these are not available, sterile intravenous tubing is of adequate size to "shunt" both the artery and the vein, if necessary. Venous shunt placement (instead of ligation) may improve extremity perfusion and lower the risk of compartment syndrome. Damage control shunt placement begins with obtaining adequate proximal and distal control. Thrombus should be cleared with a Fogarty embolectomy catheter, followed by the instillation of regional heparinized saline (5000 units heparin/500 mL saline). The shunt should be placed in a straight line and be long enough to remain safely held in place in the proximal and distal vessel with a tied umbilical tape or 2-0 silk tie at each end. Long, looped shunts run the risk of becoming dislodged during subsequent dressing changes and should be

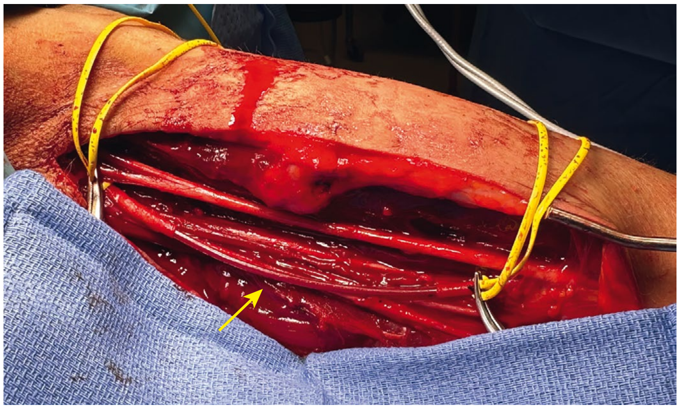

FIGURE 38.5 Brachial artery injury with large missing segment from penetrating injury. A temporary vascular shunt *(arrow)* was used to restore perfusion while the patient was resuscitated, and saphenous vein harvest was undertaken for interposition repair.

avoided. The ties securing the shunt cause intimal damage, and those portions of the artery must be resected at the time of definitive vascular repair.

Role of Fasciotomy

Failure to perform an adequate fasciotomy after revascularization of an acutely ischemic limb is the most common cause of preventable limb loss.[5] Calf compartment syndrome is the most common indication for fasciotomy. Forearm and thigh compartment syndromes are less common. Any muscle group can develop compartment syndrome, including those in the hands and feet.

Compartment syndrome may be manifested immediately or delayed to 12 to 24 hours after reperfusion. If it is not promptly diagnosed and treated, the risk of limb loss or limb dysfunction is high. Calf compartment syndrome most commonly results from prolonged ischemia or a crush injury. Frequent physical examinations augmented with compartment pressure measurements are necessary to detect this complication in its early stage. The first clinical findings are pain and loss of light-touch sensation in the distribution of the nerve in the compartment. The diagnosis of compartment syndrome should be suspected in any patient complaining of increasing pain after injury. Other physical findings include a tense compartment, pain on passive range of motion, progressive loss of sensation, and weakness. The loss of arterial pulses is a late finding, which usually indicates a poor prognosis. Neurologic signs and symptoms, although helpful, are neither sensitive nor specific in the upper extremity after arterial injury because associated peripheral nerve injury often exists. A high index of suspicion is especially needed in patients who are intubated and sedated, and measurement of compartment pressures can be especially useful in such cases. The normal tissue compartment pressure ranges from 0 to 9 mm Hg. Much controversy exists about what constitutes a pathologic elevation. However, the safest approach is to perform fasciotomy when compartment pressure exceeds 25 mm Hg.[5,33]

A compartment syndrome can also develop in either the upper arm (triceps, deltoid, or along the axillary sheath) or the forearm. The forearm compartment syndrome is more common. Increased tissue pressure can follow either blunt or penetrating trauma because of hematoma, posttraumatic transudation of serum into the interstitial space, venous thrombosis, or reperfusion after ischemia.[33] The possibility of a compartment syndrome must always be a consideration in a patient who has been injured, particularly one with prolonged ischemia before reperfusion.

Role of Immediate Amputation

A very limited role for primary amputation exists in the management of complex extremity vascular injuries. Patients with extensive soft tissue loss, neurologic deficit, extensive fractures, and vascular injuries should be evaluated collaboratively with orthopedic, neurosurgical, and plastic and reconstructive surgery colleagues to determine if primary amputation is the best initial management. Scoring systems to predict the need for amputation have not been useful.[34] Because of the emotional impact of amputation and because marginally viable tissue often takes hours to demarcate or declare, it may be best to proceed with initial intraoperative evaluation and documentation (pictures, radiographs, and consultation), damage control using intravascular shunts for the vascular injuries, and a second look in 24 hours. The interval of time allows communication with the patient and the family and a more planned approach. Immediate amputation should also be considered in patients with extensive soft tissue, bone, and neurovascular disruption who have life-threatening torso injuries, as mentioned earlier in the discussion of damage control techniques. If immediate amputation is required, extensive documentation of the extremity injury, with photographs (Fig. 38.6) placed in the medical record, will be helpful in later explaining the decision to the patient and family and will help with their acceptance of this drastic surgical procedure.

Resuscitative Endovascular Balloon Occlusion of the Aorta

Intraaortic balloon tamponade for trauma was first described during the Korean War and has made a comeback in recent years.[35] REBOA consists of a catheter with an inflatable balloon near the tip that is inserted via the common femoral artery into the aorta as a minimally invasive alternative to open thoracotomy and cross-clamping of the aorta to control hemorrhage below the diaphragm. This has been shown to improve overall survival, mainly in patients not requiring cardiopulmonary resuscitation.[36,37]

Although its minimally invasive nature and simple design are attractive, the use of REBOA remains a polarizing topic in trauma as the precise indications continue to be elucidated. The generally agreed-upon indication is for obtaining temporary hemorrhage control from abdominal, pelvic, and junctional injuries for patients in extremis.[38] There are three zones of occlusion where REBOA can be placed, which is determined by the suspected location of injury. Zone I is the descending thoracic aorta from the left subclavian to celiac trunk, zone II is the aorta between the celiac trunk to the lowest renal artery ("zone of nonocclusion"), and zone III encompasses the abdominal aorta from the lowest renal artery to the aortic bifurcation. REBOA simultaneously controls noncompressible torso hemorrhage and augments central and cerebral perfusion during aortic occlusion.

The outcomes of REBOA hinge on rapid arterial access and minimal occlusion time, meaning time to definitive hemorrhage control is of utmost importance. These patients are still hemodynamically unstable, and REBOA is a bridge to emergent

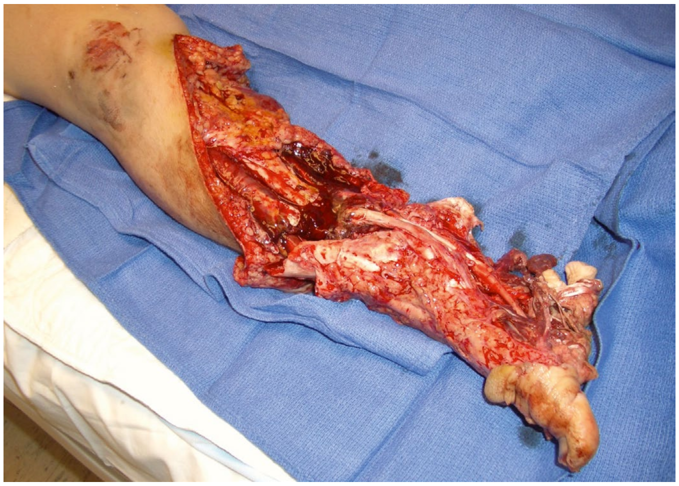

FIGURE 38.6 Major disruption of tissues in a mangled extremity after an auto-versus-pedestrian accident. After consultation with both the patient and their family regarding the severity of nerve, vascular, and soft tissue loss, a collaborative team performed an amputation.

operation. The general steps for placement include (1) determination of appropriate balloon insertion length, (2) femoral artery access below the inguinal ligament (ultrasound guided or cutdown), (3) placement of a 7-Fr sheath, (4) REBOA insertion, (5) REBOA inflation, and (6) REBOA management.[4] Occlusion time should be limited to 30 minutes in zone I and 60 minutes in zone III. Once definitive hemorrhage control has been achieved, the balloon should be deflated gradually over 5 minutes. The catheter and sheath should be removed.

Complications from REBOA include access site hematoma, pseudoaneurysm, thromboembolism, arteriovenous fistula, compartment syndrome, and vessel rupture resulting from inappropriate positioning (Fig. 38.7). These patients are also at high risk for systemic responses secondary to occlusion of the aorta in combination with massive resuscitation, including acute respiratory distress syndrome (ARDS), ischemia-reperfusion injury, acute kidney injury, and multisystem organ failure.[4] A recent analysis of the American College of Surgeons Trauma Quality Improvement Program (TQIP) database found an increased incidence of kidney injury, lower extremity amputation, and mortality in a matched analysis between patients who received REBOA versus those who did not.[39] Furthermore, the recently published UK-REBOA Randomized Clinical Trial compared REBOA to standard care and concluded that in the emergency department, REBOA does not reduce, and may increase, mortality compared with standard care alone.[40] It is imperative for surgeons who use REBOA to be proficient in technical placement and management and optimize patient selection to mitigate complications and improve outcomes in this subset of patients.

MANAGEMENT OF SPECIFIC INJURIES

Neck Injuries

Vascular injuries of the head, neck, and thoracic outlet are often challenging to manage. Penetrating trauma can injure large vessels, such as the innominate and subclavian arteries, which can lead to exsanguination. Blunt trauma to the carotid and vertebral arteries, collectively known as *blunt cerebrovascular injuries,* is often occult and, if not diagnosed and treated rapidly, can lead to cerebral ischemia, infarction, and possibly death.

Penetrating

The management of penetrating neck trauma has historically been based on the location of the injury relative to the three zones of the neck: zone I, inferior to the cricoid cartilage; zone II, cricoid cartilage to the angle of the mandible; and zone III, cephalad from the angle of the mandible. This anatomic classification required exploration for any zone II injury. This resulted in a high rate of negative neck explorations, with up to 50% being nontherapeutic.[4] The management has since evolved to be more selective, and the paradigm has shifted to a "no-zone" approach. Patients with penetrating neck trauma and hard signs of vascular injury should undergo immediate exploration, regardless of zone. Patients who are hemodynamically stable and without hard signs of vascular injury should be evaluated with physical examination and CTA. The classic zones of neck injury are still helpful in describing the anatomic location, locating potential injured structures, and planning for intervention.

In a stable patient with a suspected vascular injury in either zone I or zone III, vascular imaging is mandatory to confirm the suspicion of vascular injury and plan proximal and distal control.[41] Vascular imaging is also recommended for stable patients with penetrating trauma in zone II, but exploration should be undertaken expeditiously for patients with an expanding hematoma or impending airway compromise (manifested by hoarseness and tracheal deviation).[41] In the unstable patient, a Foley urinary catheter with the balloon inflated can be inserted into the wound to achieve temporary tamponade of injuries in these regions. Conventional angiography can have a dual role for injuries in zone I or zone III. It not only can provide the diagnosis but also may provide a venue for endoluminal management—coiling of bleeding vessels or pseudoaneurysms in zone III or placement of covered stents in zone I.

Vascular injuries of the thoracic outlet are challenging because they involve large-caliber vessels that can be difficult to expose and control. Unstable patients with vascular injury in the region of the thoracic outlet must be expeditiously taken to the operating room. Stable patients should have preoperative imaging with catheter angiography or CTA to locate the injury and determine its extent. This will allow planning for endoluminal treatment or open exposure. Operative control may require a simple supraclavicular incision, a sternotomy, or a combination of the two incisions, depending on the location and extent of the injury. Clamp application on the proximal subclavian and carotid arteries must be precise to avoid injury to the vagus, phrenic, or recurrent laryngeal nerves, all of which reside in this anatomic region. Sternotomy is frequently used for proximal innominate, proximal right subclavian, and proximal right carotid arterial injuries. Left subclavian artery proximal control may be difficult through sternotomy alone and may require concomitant clavicular incision or third intercostal space anterolateral thoracotomy. Distal control of the carotid arteries is obtained by extending the median sternotomy superiorly along the border of the ipsilateral sternocleidomastoid muscle. Distal subclavian arterial control is obtained through a clavicular incision. Resection of the clavicle results in little or no morbidity and can be performed quickly to control hemorrhage if needed. Suturing of the subclavian and axillary arteries must be done with extreme caution. Undue tension or traction will result in a tear of these fragile vessels. Endovascular balloon occlusion, when it is rapidly available, is an excellent adjunctive measure for proximal control.

Blunt Cerebrovascular Injury

Blunt cerebrovascular injuries (BCVIs) are often occult and asymptomatic. Therefore, rapid diagnostic screening is essential and provides the underpinning of successful management.[29,30] Initially, BCVIs were thought to be rare, occurring in about 0.1% of patients, but with use of the screening criteria developed by the group at Denver General Hospital, the incidence is actually 10 to 20 times that.[29] Factors associated with these injuries include displaced midface fractures, basilar skull fracture with carotid canal involvement, cervical spine fracture, closed head injury consistent with diffuse axonal injury and Glasgow Coma Scale score below 6, and blunt neck trauma from hanging or seat-belt injuries. Both carotid and vertebral artery injuries occur from stretching or tearing of the intima of the vessels produced by rapid extreme extension or flexion of the neck or by direct blunt-force injury. The carotid artery is particularly vulnerable where it lies close to the second and sixth cervical transverse processes. The vertebral artery is also vulnerable to stretch injuries and fractures of the transverse process of the cervical vertebrae that involve the foramen transversarium. Cerebrovascular injuries vary from minor intimal irregularities to arterial rupture and severe hemorrhage.[29] The grading of these injuries is detailed in Table 38.2.

Patients who fulfill the Denver criteria should undergo CTA of the neck.[7,29] The treatment of blunt carotid and vertebral artery injuries is antiplatelet or anticoagulation in patients who do not have a contraindication.[28] Antiplatelet agents like aspirin are often the only alternative in patients who cannot be systemically anticoagulated. The use of endovascular techniques has a very limited role, as discussed earlier. However, in patients with carotid injuries at the base of the skull or injuries of the vertebral artery, covered stents or embolization offers the best results.

Chest Injuries

Great Vessels

Penetrating injuries of the intrathoracic great vessels (aorta, superior and inferior venae cava, pulmonary arteries and veins) usually cause death at the time of injury from exsanguination. The small number of patients with penetrating injuries of the intrathoracic great vessels who arrive to the trauma center alive often present with hemodynamic instability and require emergent operative intervention. Repair of intrathoracic great vessel injuries may be achieved through sternotomy, left or right anterolateral thoracotomy, or in many cases, bilateral (or clamshell) anterolateral thoracotomy.[42] Although many of these structures are exposed through a posterolateral thoracotomy in the elective setting, patients who present in hemorrhagic shock and without a distinct diagnosis should be managed with more versatile incisions, such as median sternotomy and anterolateral thoracotomy.

TABLE 38.2 Grading Scale for Blunt Cerebrovascular Injury (BCVI)

Grade I	Irregularity of the vessel wall or a dissection/intramural hematoma with ≤25% luminal stenosis
Grade II	Intraluminal thrombus or raised intimal flap is visualized, or dissection/intramural hematoma with >25% luminal narrowing
Grade III	Pseudoaneurysm
Grade IV	Vessel occlusion
Grade V	Vessel transection

Injuries to the ascending aorta and the superior or inferior vena cava are best exposed and treated through a median sternotomy.[42] These injuries should be controlled with digital pressure and then placement of a side-biting clamp to allow suture repair of the injury, and they may require cardiopulmonary bypass to achieve repair. Injuries of the descending aorta are ideally approached through a left posterolateral thoracotomy. However, most of these injuries will be discovered during emergent left anterolateral thoracotomy and will need to be quickly repaired. Injuries of the pulmonary arteries and veins can be approached through a sternotomy or anterolateral thoracotomy, depending on their proximity to the heart.[42] If possible, these injuries should be repaired primarily. However, destructive injuries to the pulmonary arteries and veins may necessitate pneumonectomy for definitive control.

As endovascular techniques continue to develop, their role in management of great vessel injury has increased greatly in recent years. The decision for this approach should take into consideration the mechanism of injury, hemodynamic stability, and ease of arterial access. Although, as previously noted, penetrating injuries to this location often lead to expiration in the prehospital setting or severe instability upon initial presentation, blunt injuries may often present in a much more stable manner. These injuries are increasingly being managed with the use of endovascular stents, such as thoracic endovascular aortic repair (TEVAR).[26]

Blunt Thoracic Aortic Injury

Blunt injuries to the intrathoracic great vessels consist primarily of blunt thoracic aortic injury (BTAI). BTAI occurs as a result of high-energy blunt trauma. The most common mechanisms of injury resulting in BTAI are high-speed motor vehicle crashes and falls from a height. The aorta is typically injured in a location where it is relatively fixed (root of the aorta, ligamentum arteriosum, diaphragmatic hiatus), and the majority (85%–90%) of patients die at the scene. Patients with BTAI who arrive at the hospital alive have typically sustained multisystem associated injuries. BTAI must be ruled out when there is a high-energy mechanism of injury or a chest radiograph shows a widened mediastinum. Traditionally, such findings on chest x-ray as widened mediastinum or loss of the aortopulmonary window were thought to be diagnostic for BTAI. However, recent literature has shown these classically taught findings to be unreliable and present in approximately 58% of all patients with BTAI.[43] Definitive diagnosis of BTAI is established with a high-resolution CT scan of the chest. Injuries vary from an intimal injury to pseudoaneurysm or a contained periaortic hematoma just distal to the left subclavian artery.[6]

Once the diagnosis of BTAI is confirmed, the initial management is focused on blood pressure control while addressing associated immediately life-threatening injuries, followed by endovascular repair of higher-grade injuries.[44] Blood pressure is best controlled with a short-acting intravenous β-blocker (e.g., esmolol) that can be titrated to a systolic blood pressure of less than 110 mm Hg while also keeping heart rate below 100 beats/min, should baseline comorbidities and injury burden allow this.[42] If β-blockade does not achieve blood pressure goals, other intravenous agents, such as calcium channel blockers, nitroglycerin, and nitroprusside, may be used. Lower-grade injuries (grade I [intimal tear], grade II [intramural hematoma]) can generally be managed without intervention and only require blood pressure control and repeat imaging (Table 38.3). Grade III injuries (pseudoaneurysm) should be repaired in a delayed fashion after stabilizing other life-threatening injuries. The most severe injuries (grade IV [rupture]) should be managed urgently to prevent exsanguination.

Open repair of BTAI was the mainstay of treatment for decades. Open repair is achieved through a left posterolateral thoracotomy, cardiopulmonary bypass, and placement of a synthetic aortic interposition graft. However, TEVAR has become the standard of care for the surgical management of BTAI. The advent of new and improved stent grafts and the widespread adoption of endovascular techniques have made this approach the first choice at most centers. Although there are no prospective, randomized trials comparing open versus endovascular management of BTAI, there have been two multicenter American Association for the Surgery of Trauma trials showing lower morbidity (spinal cord ischemia, stroke) and mortality with the endovascular approach.[26,27] However, patients who undergo endovascular repair require lifelong surveillance because there is no information about long-term sequelae of endovascular grafts in the aortic position in young patients. In addition, some young patients may not have favorable anatomy for endovascular repair and still require the open approach.

TABLE 38.3 Grading Scale for Blunt Thoracic Aortic Injury (BTAI)

Grade I	Intimal tear
Grade II	Intramural hematoma
Grade III	Pseudoaneurysm
Grade IV	Rupture

Abdominal Injuries

Aortoiliac Injuries

Abdominal vascular injuries most often result from penetrating trauma, and all are treated through a generous midline laparotomy.[13] Many of these injuries will require supraceliac control of the aorta to achieve adequate visualization to complete exposure and repair. Penetrating injuries to the abdominal aorta are best exposed and repaired with a left medial visceral rotation that exposes the aorta from the diaphragmatic hiatus to the iliac bifurcation (Fig. 38.8). The injury can typically be controlled with direct digital pressure, which allows time for placement of vascular clamps proximal and distal to the site of injury.[13] Abdominal aortic injuries may be repaired primarily after stab wounds, but gunshot wounds will often require a patch repair or interposition graft. Uncommonly, patients will sustain a blunt abdominal aortic injury without life-threatening hemorrhage, and these injuries are best repaired by endovascular techniques (Fig. 38.9).

The right common, external, and internal iliac arteries are best exposed by widely mobilizing the cecum, whereas injuries to the left iliac arteries are exposed by completely mobilizing the sigmoid colon.[13] Keep in mind the course of the ureter on both sides as it crosses the iliac vessels. Injuries to the common and external

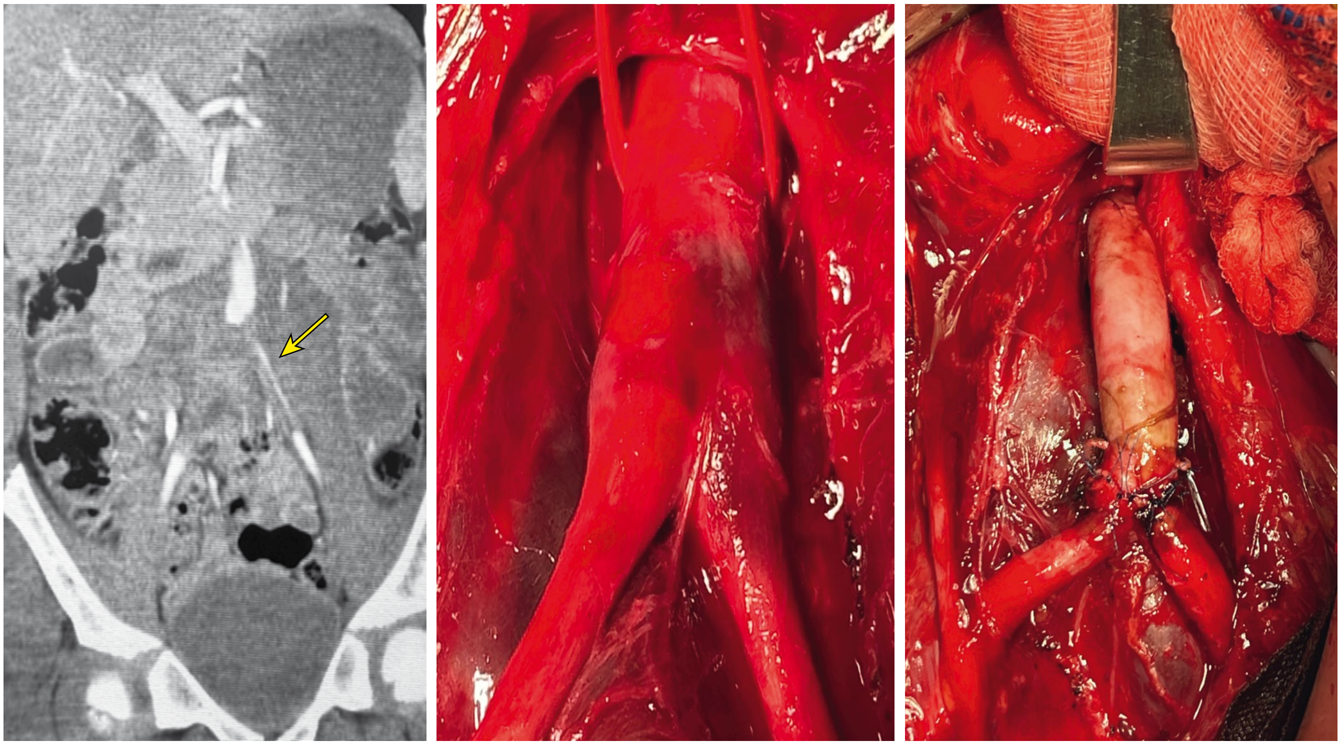

FIGURE 38.8 Pediatric seat-belt injury to the abdominal aorta with aortoiliac occlusion demonstrated on CT *(arrow, left panel)*. Open exposure revealed a contused aorta, and after vascular control and vessel entry, devastating dissection was observed. *Right panel* demonstrates interposition repair and iliac bifurcation reconstruction with cadaveric iliac artery in this very young patient.

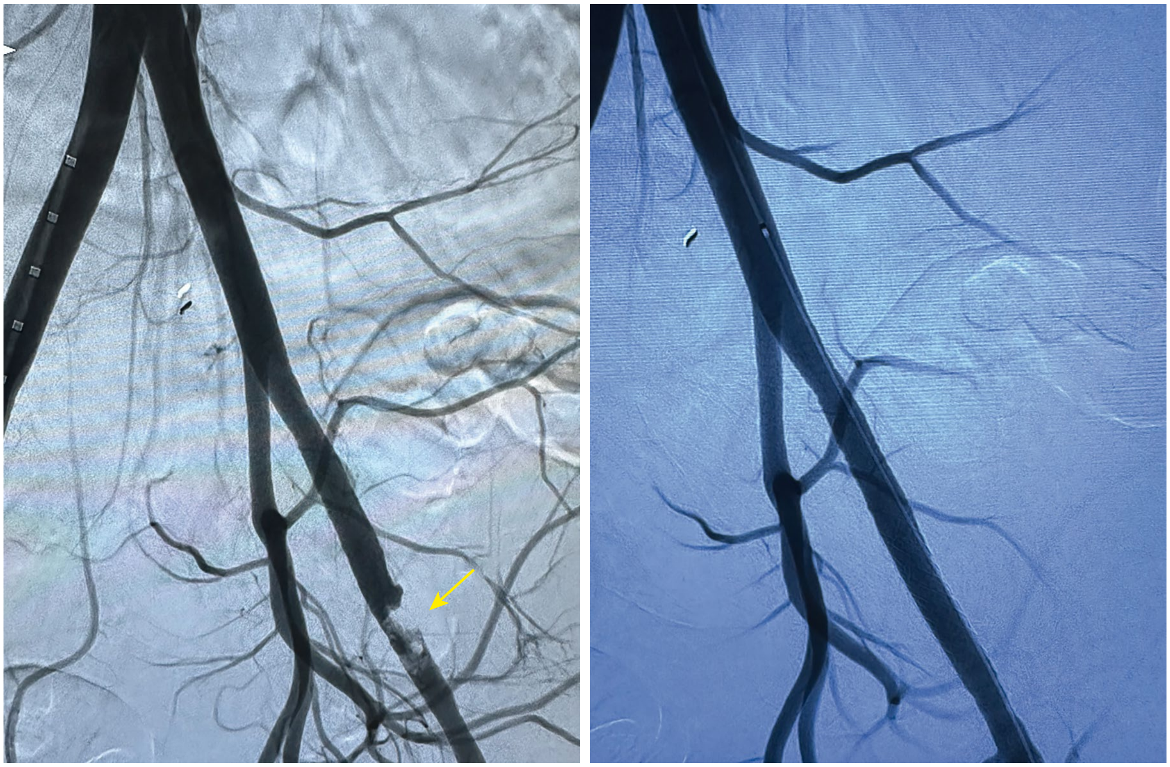

FIGURE 38.9 Blunt left external iliac artery injury *(arrow).* Angiogram after endovascular repair is demonstrated on the *right.*

iliac arteries are initially controlled with digital pressure to allow proximal and distal control with vascular clamps or vessel loops. Injuries to the common and external iliac arteries may be repaired primarily but will often require a synthetic interposition graft. The common and external iliac arteries should never be ligated; if a patient is hemodynamically unstable, these injuries should be shunted and repaired in a delayed fashion. However, injuries to the internal iliac artery can be routinely ligated.[13]

Mesenteric and Renal Arterial Injuries

Injuries to the mesenteric vessels are some of the most challenging injuries to expose and repair. In the elective setting, the celiac trunk is often approached through the lesser sac, but in the setting of trauma, this may prove difficult because of a large lesser sac hematoma that obscures the usual landmarks. In the setting of trauma, the celiac trunk is best exposed through a wide left medial visceral rotation that mobilizes the spleen and tail of the pancreas but leaves the left kidney in situ.[13] Once exposed, most injuries to the celiac trunk should be ligated because repair is difficult, and ligation is well tolerated in the majority of patients. Although the SMA and celiac trunk take off from the aorta within 1 to 2 cm of each other, the exposure and treatment algorithm for SMA injuries is different. Management of SMA injuries will depend on location based on the Fullen classification: zone I, beneath the pancreas; zone II, between the pancreaticoduodenal and middle colic branches; zone III, beyond the middle colic branch; zone IV, enteric branches. Injuries that present with a large contained central hematoma at the root of the mesentery are best approached with a left medial visceral rotation. Active hemorrhage is controlled by manual compression, followed by left medial visceral rotation.[13] This will allow exposure and control of the aorta proximal and distal to the SMA or direct clamping of the SMA as it comes off the aorta. Once this control has been achieved, attention is turned anteriorly for definitive exposure and repair of the SMA injury.

Zone I and zone II SMA injuries can be exposed and repaired through the lesser sac by dividing the gastrocolic ligament. The pancreas will need to be retracted inferiorly to expose the origin of the SMA or superiorly to expose the proximal SMA. Uncommonly, in active bleed SMA injuries behind the pancreas, it may need to be divided to completely visualize and control that segment of the SMA. Zone III and zone IV injuries should be approached by reflecting the transverse colon and its mesentery superiorly with or without taking down the ligament of Treitz. All zones of SMA injuries (except distal zone IV injuries) should always be repaired with a primary repair, end-to-end anastomosis, or interposition graft of reversed saphenous vein.[13] If the patient is in extremis, the SMA may be shunted, with a plan for delayed repair.

Penetrating renal vascular injuries are easily exposed on either side after medial visceral rotation. Gerota's fascia is opened, and the kidney is bluntly mobilized into the wound. Once the kidney is mobilized, the vascular injury can be controlled with direct manual pressure while proximal and distal control is obtained with vessel loops. Renal artery injuries can be managed with primary repair, end-to-end anastomosis, vein patch, interposition graft, or nephrectomy (after confirming a normal contralateral kidney by palpation). Treatment of renal artery injuries is based on complexity of the injury and physiologic status of the patient. Combined injuries to the renal artery and vein should be treated with nephrectomy in unstable patients. Renal artery injuries rarely occur after blunt trauma. These injuries may be managed nonoperatively, with expected involution of the affected kidney or nephrectomy. It is uncommon to successfully salvage renal function with vascular reconstruction of complete blunt renal artery occlusion. Management must consider several factors, including overall status of the patient, warm ischemia time, and need for laparotomy for associated intraabdominal injuries.

Abdominal Venous Injuries

The inferior vena cava is exposed with a right medial visceral rotation that exposes the vena cava from the iliac vein confluence to the inferior edge of the liver.[13] Injury to the vena cava is best controlled with direct digital pressure, with subsequent proximal and distal control using sponge sticks or vessel loops. Lumbar tributaries and renal veins may also need to be controlled to clearly visualize and repair the injury. Injuries to the anterior or lateral surfaces of the vena cava can most often be repaired primarily as long as the repair does not narrow the lumen more than 50%. Penetrating injuries to the vena cava may be through-and-through injuries and require repair of a posterior injury as well. Injuries to the posterior vena cava may be repaired through the anterior injury, or the vena cava may be mobilized after ligating and dividing lumbar veins. Complex injuries may require patch repair, interposition graft, shunting with delayed reconstruction, or ligation.[13] The complexity of repair will depend on the physiologic status of the patient and the location of the injury. Hemodynamically unstable patients with ongoing hemorrhage are not candidates for complex repairs and should have the vena cava ligated or shunted. Hemodynamically stable patients with injuries at or above the level of the renal veins may be candidates for complex reconstruction, but ligation is still an option for the exsanguinating patient.[13]

Iliac veins are exposed in the same manner as iliac arteries. Exposure is made more challenging by the location of the confluence of the iliac veins with the inferior vena cava directly posterior to the right common iliac artery. It will need to be widely mobilized to allow access to the confluence of the iliac veins. However, we do not advocate division of the right iliac artery to achieve exposure of the iliac vein confluence. Once the common, external, and internal iliac veins are exposed, the injury is best controlled with direct digital pressure; then proximal and distal control may be achieved with vessel loops. If possible, simple injuries to the iliac veins should be repaired with primary venorrhaphy. However, complex repairs of destructive injuries to the iliac veins should not be attempted, and these injuries should be ligated.[13]

The superior mesenteric vein (SMV) can be exposed in the same fashion as the SMA. SMV injuries should be repaired or reconstructed when possible, although shunting with delayed repair is also an option. The SMV may be ligated for patients in extremis who would otherwise exsanguinate. Injuries to the inferior mesenteric artery may be ligated if there is adequate collateral flow from the middle colic branch of the SMA and the inferior and middle hemorrhoidal branches of the internal iliac arteries. The inferior mesenteric vein may be safely ligated if required.

The portal vein runs close to the inferior vena cava and is the most posterior structure within the portal triad, closely associated with the common bile duct and hepatic artery. Portal vein injuries are initially controlled with direct manual pressure. A right medial visceral rotation, including a generous Kocher maneuver, is performed to expose and visualize the lateral and inferior portal vein. The common bile duct and hepatic artery will need to be mobilized to expose the anterior surface of the portal vein. Similar to SMA and SMV exposure, the neck of the pancreas may need to be divided to visualize the entirety of the portal vein.[13] These injuries should be managed in the same fashion as SMV injuries, with repair or reconstruction in the majority of cases, shunting and delayed repair if necessary, and ligation only for patients in extremis who would otherwise exsanguinate.

Renal vein injuries can be repaired with primary venorrhaphy or ligation. On the right, ligation of the renal vein will require a nephrectomy, and patch angioplasty or interposition graft may be considered in stable patients. The left renal vein may be safely ligated near the inferior vena cava because of collateral flow through the left adrenal, gonadal, and lumbar veins.[13]

Extremity Injuries

Upper Extremity

Penetrating injury often presents with a history of either arterial hemorrhage or ongoing bleeding. Blunt injury usually causes thrombosis and the signs of acute arterial occlusion with resultant ischemia. Significant neurologic injury, usually involving the median nerve, is present in 60% of patients with upper extremity arterial injury.[5,45] Concomitant venous injury is common. In the setting of multisystem injury, arterial occlusion in the upper extremity is easily missed. Delay in diagnosis resulting in prolonged ischemia is an important contributing factor to preventable limb loss or long-term disability from irreversible ischemic nerve injury. All significant vascular injuries of the upper extremity result in clinical findings that are apparent on thorough physical examination. Unfortunately, associated severe torso or lower extremity injuries distract the trauma team from the injured and ischemic upper extremity. Delays in diagnosis and treatment are common in collected series of patients with upper extremity arterial injury and are more common after blunt-force trauma.[5,45]

The diagnosis of upper extremity arterial injury is often made on physical examination alone, particularly in penetrating injuries. Noninvasive evaluation of the injured upper extremity adds little to a thorough history and physical examination. Patients with obvious arterial or venous lacerations from penetrating trauma or those with blunt trauma and hard findings should be taken directly to the operating room. The arterial bed of the upper extremity is extremely reactive to vasoconstriction produced by hypovolemic shock, pain, and drugs, including cocaine and methamphetamine. Absent pulses in the presence of complex fractures or crush injuries of the upper extremity need to be assessed with imaging (either multidetector CT or conventional angiography) if normal perfusion does not return after resuscitation and the administration of adequate pain medications.

There is currently not a role for endovascular therapy in the brachial artery and forearm vessels. Traditional operative exposure, catheter thrombectomy, and repair remain the best approaches to optimize results.[5,45] In patients unstable from associated torso injuries, damage control with arterial shunt placement followed by repair when the patient is hemodynamically stable is the best management option. Vascular injuries in the upper extremity are often associated with significant musculoskeletal, neurologic, and soft tissue injuries. When this occurs, a multidisciplinary approach is often required with orthopedics, neurosurgery, and plastic surgery. Venous injuries of the upper extremity can be ligated unless there is extensive soft tissue injury and loss of venous collaterals. In that setting, some form of venous reconstruction should be considered.

On occasion, bleeding from a partially transected arm or forearm vessel can be significant. The surgeon should make certain that adequate control is obtained and maintained during resuscitation, transportation to the operating room, and surgical preparation and draping. Tourniquets have proved lifesaving in the field for management of hemorrhage from extremities, and they have a role in the trauma bay for obtaining hemorrhage control during resuscitation and a timely, thorough evaluation for other injuries. Tourniquets from the field or applied in the trauma bay should be carefully monitored for both adequacy of compression and duration of application by the senior surgeon present.

The patient should be widely prepared and draped with generous inclusion of the entire upper extremity, the shoulder, and the anterior-superior aspect of the chest to allow incisions for proximal control.[5] An uninjured leg should also be prepared and draped from the inguinal region to the toes to allow saphenous vein harvest. Adjunctive measures, such as bolus intravenous systemic heparinization, administration of a continuous infusion of low-molecular-weight dextran, and administration of intravenous antibiotics, should be considered and used where appropriate. In patients with multisystem injuries, especially head injury, local or regional infusion of heparin should be used in place of systemic administration. Loupe magnification and coaxial lighting ("headlight") are technical adjuncts that may be useful in suturing small blood vessel with fine suture.

Surgical exposure requires generous incisions placed to maximize exposure and provide appropriate options for further exploration and repair. The brachial artery is best exposed through a longitudinal incision along the medial aspect of the upper arm over the groove between the triceps and biceps muscles. The incision can be extended distally with an S-shaped extension across the antecubital fossa from the ulnar to radial aspect and onto the forearm to expose the origins of the forearm vessels.[5,45] Proximal brachial artery injuries may require control of the infraclavicular axillary artery. Vascular repair requires attention to detail in all phases. Balloon catheter thrombectomy and flushing with heparinized saline followed by debridement of damaged arterial wall are essential to successful repair. Lacerated veins should be ligated. If the duration of arterial occlusion and ischemia is a concern, temporary intraluminal shunts may be placed in the artery. Primary arterial repair of undamaged ends of vessels (end-to-end anastomosis) should be performed only if the repair is tension free. Saphenous vein interposition should be chosen whenever vessel injury is extensive or if primary tension-free repair is not possible. PTFE needs to remain a second choice to autologous vein in the management of injuries of the brachial artery and forearm vessels.[2,5,45] Forearm fasciotomy, particularly in the setting of prolonged ischemia, should be considered before completion of the operation, and patients should be followed closely for the development of postoperative compartment syndrome.

There is a limited but important role for "primary" or early amputation in the management of upper extremity vascular injuries. Patients with extensive soft tissue loss or with scapulothoracic dissociation who have severe neurologic deficits, extensive fractures, and vascular injuries should be evaluated collaboratively with orthopedic, neurosurgery, and plastic surgery colleagues to determine whether early amputation is appropriate. The best approach is intraoperative, multidisciplinary assessment; damage control; and a plan for reoperative assessment in 24 to 48 hours. This will allow discussions with the patient and family and a second look.

Combined ulnar and radial artery injury in the forearm requires repair of at least one vessel. The ulnar artery is usually larger in the proximal forearm and is a better target for direct repair or saphenous vein bypass. Distally, the vessel repair should be performed in whichever vessel is largest or amenable to simple repair.[5,45]

Isolated ulnar or radial artery injuries can be managed with simple ligation only if there is absolute certainty that flow through the remaining vessel is adequate. Close inspection of the forearm and hand with palpation of pulses augmented by continuous-wave (handheld) Doppler interrogation is essential.[5]

Lower Extremity

Vascular injuries in the legs are more common in military settings (30%–40%) than in civilian practice (20%).[46] Although penetrating injuries are more common, blunt vascular trauma in the lower extremity remains a significant challenge. In the thigh and the leg, fractures and dislocations can be associated with vascular injuries. The popliteal artery is at particularly high risk of injury after dislocation of the knee.[46]

Findings at presentation vary from significant hemorrhage from a wound (i.e., open fracture, stab, or gunshot) to occult arterial occlusion from blunt injury. A systematic approach with a thorough extremity vascular examination is essential to avoid errors in recognition and delays in treatment.

Exposure is obtained with incisions used for elective surgical procedures. The common femoral artery is best exposed through a longitudinal incision overlying its course from the inguinal ligament inferiorly for 8 to 12 cm. Proximal control may require exposure of the external iliac artery, best accomplished through an oblique muscle-splitting lower-quadrant abdominal incision carried into retroperitoneum, where the artery and vein can be controlled. SFA injuries are best exposed through a longitudinal groin incision similar to that used for femoral bifurcation exposure for the proximal portion. The mid-SFA is approached through an oblique incision over the sartorius muscle. The junction of the SFA and popliteal can be exposed by extending this incision, dividing the adductor tendon.

Popliteal injuries are exposed through a generous medial incision. Exposure of the artery in the area at the knee joint requires division of the medial head of the gastrocnemius muscle and the semimembranosus and semitendinosus muscles. The distal popliteal artery is exposed with an incision along the posterior margin of the tibia.

Repair of lower extremity vascular injuries usually requires an interposition graft (Fig. 38.10). This is particularly true in the popliteal artery. Reverse saphenous vein from the contralateral extremity is the first choice for interposition grafts. In the common femoral artery, PTFE is an acceptable choice for interposition if the saphenous vein is not of sufficient size. However, saphenous vein remains the best graft for repair of the superficial femoral, popliteal, and tibial vessels.[16] Similar to the upper extremity, fasciotomy of the lower leg should be considered before completion of the operation, particularly with prolonged ischemia, and patients should be followed closely for the development of postoperative compartment syndrome.

Injuries below the popliteal artery at the level of the tibial vessels are best managed by ligation if two of the three calf vessels are patent and there is adequate collateral flow. In the presence of both anterior and posterior tibial vessel occlusion, the peroneal artery is usually not sufficiently connected to the distal arterial bed by collaterals, and repair of one of the injured vessels should be performed. The choice of which vessel to repair is based on both the extent of associated soft tissue injury and the patency of the distal segments of those vessels.

Damage control techniques with arterial and venous shunt placement with delayed definitive repair are an important part of managing lower extremity vascular injury associated with major torso

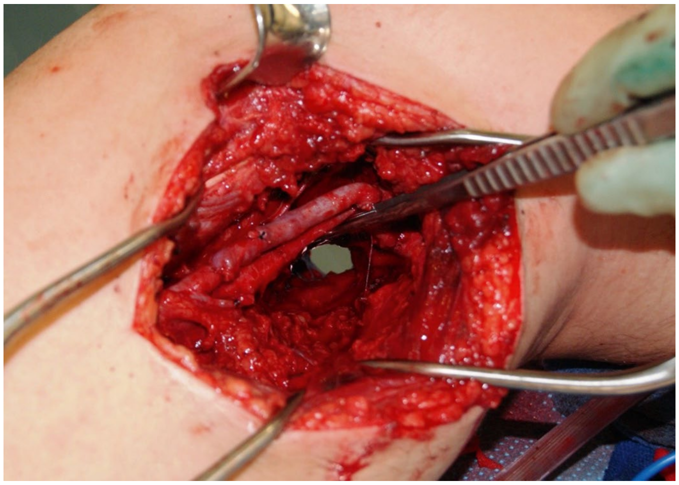

FIGURE 38.10 Interposition repairs of left distal femoral artery and vein using greater saphenous vein. The injury location corresponded well with a traditional medial vascular exposure. The bullet wound tract after debridement can be seen extending through to the other side of the leg.

injuries and hemodynamic instability. All efforts should be made early postoperatively to achieve adequate stability as rapidly as possible to allow a timely return to the operating room for definitive vascular repair before shunt thrombosis and prolonged ischemia.

COMPLICATIONS

Despite advances in modern trauma care, morbidity and mortality after vascular trauma remain significant. The anatomic location and mechanism of the injury heavily influence the outcomes in this patient population. Emergent vascular repair also carries higher rates of morbidity and mortality compared with elective vascular surgery populations.

Cerebrovascular injury carries the risk of both mortality and debilitating stroke. The most important factor in decreasing morbidity in this injury pattern lies in initial recognition and diagnosis. Early initiation of antithrombotic therapy with either heparin or aspirin is extremely important in reducing stroke rates. Although the majority of BCVIs may initially be managed nonoperatively in this manner, close follow-up imaging and neurologic monitoring are paramount. In those managed with antithrombotic therapy, hemorrhage also carries a significant risk if the patient has concomitant injuries. Careful risk and benefit assessment should occur before initiation.[47]

Local complications such as infection, nerve injury, and lymphatic injury can also occur with vascular repair. Lymphatic injury may result in lymphedema, lymphocele formation, chylothorax, or chylous ascites. Management may include simple drainage of the lymphocele or mechanical massage to the affected area to promote lymphatic drainage. Lymphatic bypass may also be an option in select patients. Chylothorax and chylous ascites are decidedly rare, although management may include drainage, dietary modification with limited long-chain fatty acid intake or total parenteral nutrition (TPN) initiation, and identification of the source. Nerve injury often occurs at the time of the index injury, not during vascular repair. However, care must be taken during repair to identify adjacent nerve bundles and avoid further trauma. If a nerve injury is identified, early repair has been associated with improved outcomes. If this is not possible at the time of initial operation, tagging the nerve is useful for future identification and repair. Traumatic vascular injuries, particularly those repaired with nonautologous grafts, are at high risk of infection. These injuries often coexist with local soft tissue or bony injury as well as other factors like hypotension, hypothermia, and metabolic abnormalities, all of which may impair proper wound healing. It is therefore of the utmost importance to use prophylactic preoperative antibiotics, such as a second-generation cephalosporin, and sterile technique whenever possible. Surgical site infections should be managed with the attempt to separate vascular repair from infection. If a graft or repair becomes infected, risk of vascular anastomotic blowout increases. Antibiotics should be broadened, and cultures should be obtained if able. Decision-making should then become focused on either excision and revision or attempted salvage, although this is often nuanced and patient dependent.[4]

Aside from local complications, repairs themselves are associated with their own complications, including anastomotic complications, bypass thrombosis, fistula formation, endoleaks, and dissection. Anastomotic disruption, stricture, and pseudoaneurysm are all potentially devastating occurrences. Care must be taken to provide a durable and fully patent anastomosis during repair. The use of on-table angiography or a hybrid suite can be useful in evaluating the adequacy of a repair before leaving the operating room. Bypass thrombosis has many factors but can threaten life and limb. Attention must be given to conduit material, wound bed preparation, adequate inflow and outflow, and anastomotic sites. Aortoenteric fistulas, although rare, may be heralded by gastrointestinal bleed, abdominal pain, systemic septic characteristics, and graft thrombosis. Principles of management include resuscitation, use of broad-spectrum antibiotics, graft explanation, and revascularization. Endoleaks, or persistent arterial flow around an endovascular stent graft, are defined as types 1 through 5. Type 1 involves flow around the proximal or distal extent of the stent, and these leaks often require further intervention for repair. Type 2 results from back-bleeding from a branch vessel covered by the stent. These leaks often have a benign course and may self-resolve without need for intervention. Type 3 occurs with leakage at stent junctions, often where there is inadequate overlap of stents. This also often requires repair. Types 4 and 5 occur from graft porosity or the theoretical phenomenon of endotension. As stent graft technology has progressed, type 4 and 5 endoleaks have become rare within the elective setting and exceedingly so after vascular trauma repair.[48]

Damage Control Situations

BACKGROUND ON UROLOGIC TRAUMA

Approximately 10% to 15% of all abdominal and pelvic trauma involve the genitourinary system. Isolated urologic injuries are uncommon because the genitourinary tract is well sheltered within the abdominal cavity. Often these injuries can be subtle, yet their prompt diagnosis is essential to avoid serious complications. Initial management should include obtaining hemodynamic stability and determining the mechanism of injury because visceral organ injury patterns can vary based on mechanism of injury. A thorough physical examination can provide insight into possible injuries to deeper organs within the retroperitoneum or pelvis. Patients who are deemed to be hemodynamically stable and without life-threatening injuries should have advanced imaging to evaluate and stage abdominal and pelvic injuries.

Although initial assessment and management are typically done by emergency physicians or general surgeons, early collaboration with urologists can be critical. For example, as management of renal injuries has evolved, conservative approaches with observation, embolization, or renorrhaphy can aid in preserving renal function. Urologic expertise can augment the care of urologic trauma. Early consultation can help guide imaging and management strategies in conjunction with the emergency and surgery teams.

GUIDELINES FOR UROLOGIC TRAUMA MANAGEMENT

The Organ Injury Scaling system of the American Association for the Surgery of Trauma (AAST) has developed a long-standing grading system for different types of organ injuries. Trauma guidelines from the European Association of Urology and the American Urological Association (AUA) were developed by integrating these scaling systems into the management algorithms. The AUA initially created a urologic trauma guideline in 2014 and recently updated the guidelines in 2020.[1,2]

RENAL TRAUMA

Approximately 80% of renal trauma is the result of blunt trauma, and the remainder are penetrating injuries. Physical examination should focus on identifying the location of impact, assessing the flank, and examining the urine for microscopic or gross hematuria. For penetrating injuries, it is important to identify entry and exit points.

In evaluating renal injuries, it is important to note that the AAST recently updated the long-standing renal injury scale to reflect contemporary data on diagnosis and management of renal trauma (Table 39.1).[3,4] The original grading system that was devised in 1989 was based on anatomic findings, largely found during surgical exploration, and was used to standardize research efforts. The revised staging system has incorporated current data regarding management of high-grade renal trauma and radiologic findings.

Recent research from the Multi-institutional Genito-Urinary Trauma Study (MiGUTS) has shed light on potential additional changes that can be addressed in future revisions of the renal trauma injury scale.[5–14] Some changes in the updated renal injury scale remain controversial because of ambiguity and upstaging of certain injuries.[15,16] Particularly, segmental vascular injuries to the

TABLE 39.1 Organ Injury Scaling System: Kidney

GRADE	DESCRIPTION	AIS SEVERITY
I	• Subcapsular hematoma or parenchymal contusion without laceration	2
II	• Perirenal hematoma confined to Gerota fascia • Renal laceration ≤1 cm depth without urinary extravasation	2
III	• Renal laceration >1 cm depth without urinary extravasation • Any injury in the presence of a kidney vascular injury or active bleeding contained within Gerota fascia	3
IV	• Parenchymal laceration with urinary extravasation • Renal pelvis laceration and/or ureteropelvic junction disruption • Active bleeding beyond Gerota fascia into retroperitoneum or peritoneum • Segmental or complete kidney infarction caused by vessel thrombosis without active bleeding	4
V	• Main renal artery or vein laceration or avulsion of hilum • Devascularized kidney with active bleeding • Shattered kidney with loss of identifiable parenchymal renal anatomy	5

AIS, Abbreviated Injury Scale.
Adapted from Kozar RA, Crandall M, Shanmuganathan K, et al. Organ injury scaling 2018 update: spleen, liver, kidney. *J Trauma Acute Care Surg.* 2018;85:1119-1122.

kidney have remained a point of confusion.[16] Based on the recent staging systems, it is unclear if segmental vascular injury refers to the renal segmental arteries or just a segment of the kidney that is injured. Consequently, about a third of grade III injuries are upgraded to grade IV injuries, which increases the heterogeneity among grade IV renal injuries.[10] Importantly, the revised grading system did not outperform the 1989 grading system in predicting intervention for renal hemorrhage. Therefore, ongoing efforts are underway to propose additional changes to the kidney organ injury scale.

Imaging for Renal Trauma

Diagnostic imaging should be performed on hemodynamically stable patients when there is suspicion of renal injury based on physical examination finding or mechanism of injury. Patients with stable blunt trauma with gross or microscopic hematuria should have contrast-enhanced computed tomography (CT) of abdomen and pelvis with delayed images. Optimal delay for detection of urinary extravasation is 9 minutes.[8] In many centers, if there are no signs of kidney trauma in the contrast phase, a delayed view is not obtained; however, to limit diagnostic delay if kidney trauma is recognized by the trauma team during the contrast phase, a delayed phase is preferably pursued while the patient remains on the table. If patients are unable to have CT scans because of hemodynamic instability or require immediate intervention, a "one-shot" intravenous pyelogram (IVP) can be performed by administering 2 mL/kg contrast followed by a single abdominal radiograph, which can inform the surgeon about the presence of the contralateral kidney before considering renal exploration or nephrectomy. Several critical CT findings are important predictors for requiring intervention. Every centimeter increase in perinephric hematoma size is associated with 66% increased likelihood of requiring intervention. Additionally intravascular contrast extravasation is associated with a threefold increase in odds of requiring interventions for hemorrhage.[9,11,14]

Management of Renal Trauma

Advances in imaging, and thus staging, of renal injury have led to the evolution of the management paradigms for renal injuries (Fig. 39.1). In hemodynamically stable patients, noninvasive management, such as serial hematocrit monitoring, should be used; however, historical adjuncts such as bed rest have fallen out of favor and usefulness. Patients who are hemodynamically unstable require immediate intervention, which includes surgery or angioembolization in select patients.[17] Unstable patients with critical CT findings such as perirenal hematoma >4 cm and/or intravascular contrast extravasation should have immediate intervention. High-grade renal trauma—grade IV and V—may undergo exploration, but nephrectomy in this setting is associated with higher mortality.[6] Recent data have demonstrated that in a subset of grade V renal injuries, nonoperative management is a viable option and does not increase the length of stay for patients.[5,18,19]

Kidneys injured because of blunt trauma can often be managed conservatively, even in conditions where urinary extravasation or nonviable tissue is present. Penetrating injuries will require intervention more often when the retroperitoneum is violated based on the extent of the injury (Fig. 39.2). Nevertheless, in select cases where injuries are isolated to the kidney without abdominal involvement, conservative management should be used. After initial imaging, patients with high-grade renal trauma (AAST grade IV–V) should have repeat CT imaging to assess for urinoma, hematoma, or abscess formation. Additionally, patients with signs of complications such as fever, worsening flank pain, ongoing blood loss, and abdominal distention should be reassessed using CT imaging. Asymptomatic low-grade injuries do not require interval imaging. When a large or expanding urinoma is present, urinary drainage should be performed using a ureteral stent, and additional percutaneous drains can be added to augment drainage and promote healing.[20,21]

Surgical Exploration and Operative Approach for Renal Trauma

Absolute indications for intervention with either renal exploration or expedient angioembolization are (1) expanding, pulsatile retroperitoneal hematoma or renal pedicle avulsion, (2) hemodynamic instability that is not responsive to resuscitation, (3) suspected renal vascular pedicle avulsion, and (4) ureteropelvic junction avulsion. Relative indications for intervention are (1) urinary extravasation in a devascularized renal unit, (2) renal injury with concomitant colon or pancreatic injury, and (3) urinary extravasation from parenchymal injury.

Renal exploration should be performed through a transabdominal approach, which allows complete inspection of the viscera.[22] Renal vessels are isolated to provide vascular control if massive hemorrhage is present when Gerota fascia is opened. The small bowel is lifted out of the abdomen, and an incision is made medial to the inferior mesenteric vein and extended to the ligament of Treitz, which provides a window over the aorta at the

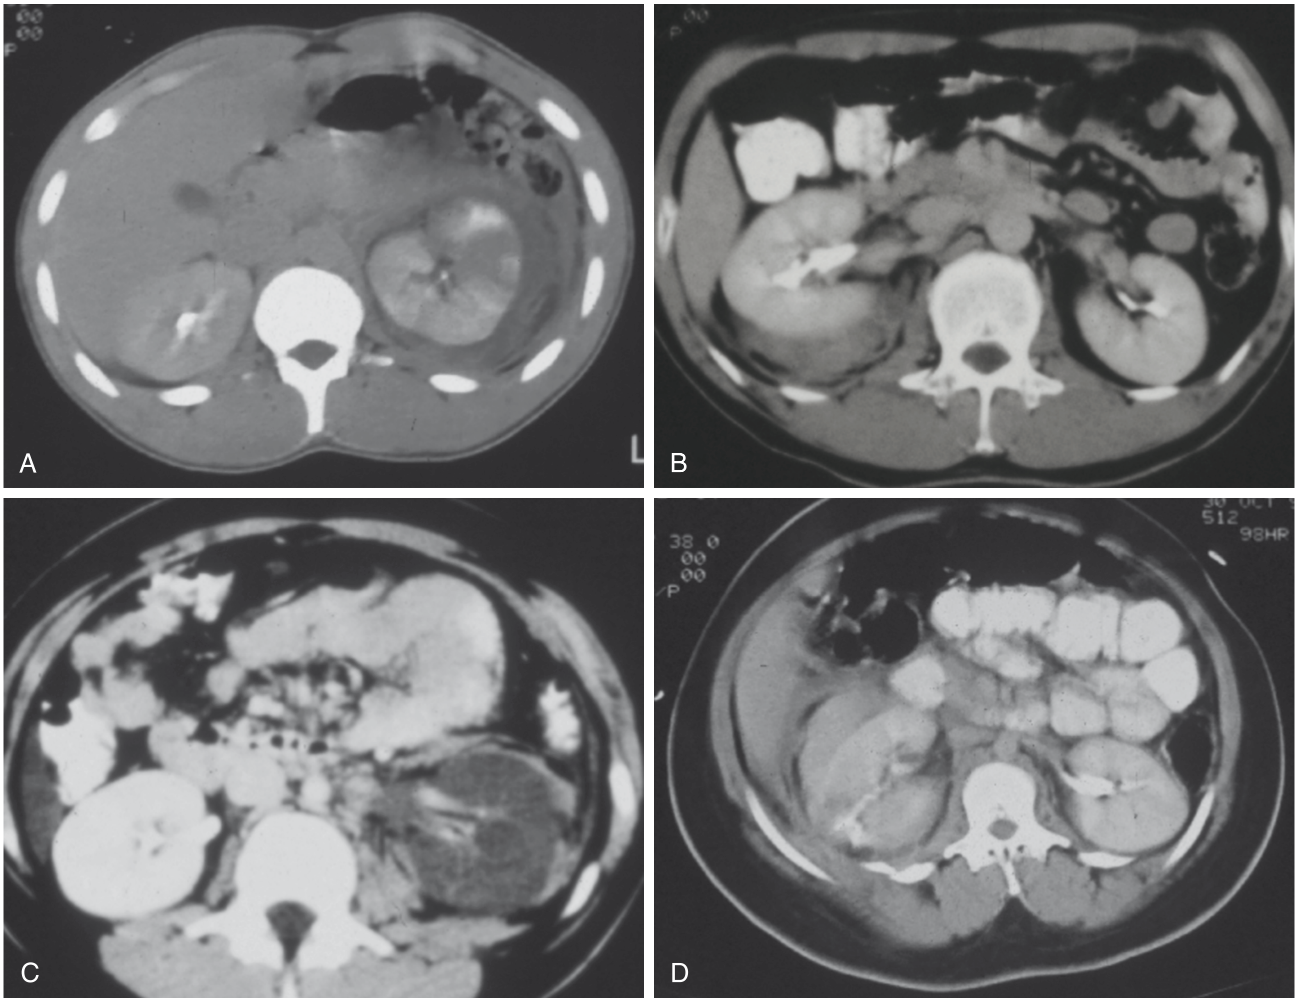

FIGURE 39.1 Computed tomography scans depicting renal trauma. (A) Grade I kidney injury with left renal contusion with heterogeneous contrast enhancement. (B) Small right posterior perirenal hematoma consistent with grade II kidney injury. (C) Grade IV renal infarction caused by left renal artery thrombosis without active bleeding. (D) Grade IV laceration to the posterolateral right kidney with posterolateral extravasation of contrast material.

level of the renal arteries. Renal vessels are controlled with individual vessel loops. Renal veins must be retracted cephalad to identify the left and right renal arteries, which run below the renal veins. If a large hematoma obscures landmarks, this approach will require dissecting through hematoma before approaching the anterior surface of the aorta. The kidney can be exposed by incising the white line of Toldt to lateralize the colon, followed by dissecting off Gerota fascia. The splenic attachments (for left) or hepatic attachments (for right) must be freed to allow mobility of the kidney.

Whenever possible, renal preservation should be a consideration, especially if urology specialists are available. Renal reconstruction requires complete exposure of the kidney, temporary vascular control, debridement of nonviable tissue, hemostasis, and closure of collecting system if needed and reapproximation of parenchymal defect. Renorrhaphy can be performed with 3-0 Vicryl suture to reapproximate the capsule over a bolster with absorbable hemostatic agent (Surgicel or Nu-Knit). If a partial nephrectomy is necessary, the collecting system should be closed, and hemostatic agents can be applied over this repair. If possible, this repair should be covered with a flap of omentum or Gerota fascia to aid with healing. A closed suction drain should be placed around the site of repair to help monitor the repair site postoperatively.

URETERAL TRAUMA

Although ureteral injuries account for 1% to 2.5% of all urologic injuries, 95% of these injuries are the result of penetrating injuries and 5% are blunt injuries. A high clinical suspicion for ureteral injury is needed based on mechanism and injury location. Because penetrating injuries, such as bullets, impart large energy transfer through a small area, damage can be as little as 2 cm away from the point of transection. Unrecognized ureteral injury is associated with significant morbidity such as urinoma, abscess, fistula formation, and possible nonfunctional renal unit. Therefore, ureters should be evaluated when evaluating other injuries.

Imaging for Ureteral Trauma

CT imaging with contrast must include delayed views to evaluate the ureter in stable patients. Extravasation of contrast, lack of contrast distal to suspected injury, or hydronephrosis can be critical findings suggestive of ureteral injury. Other imaging modalities,

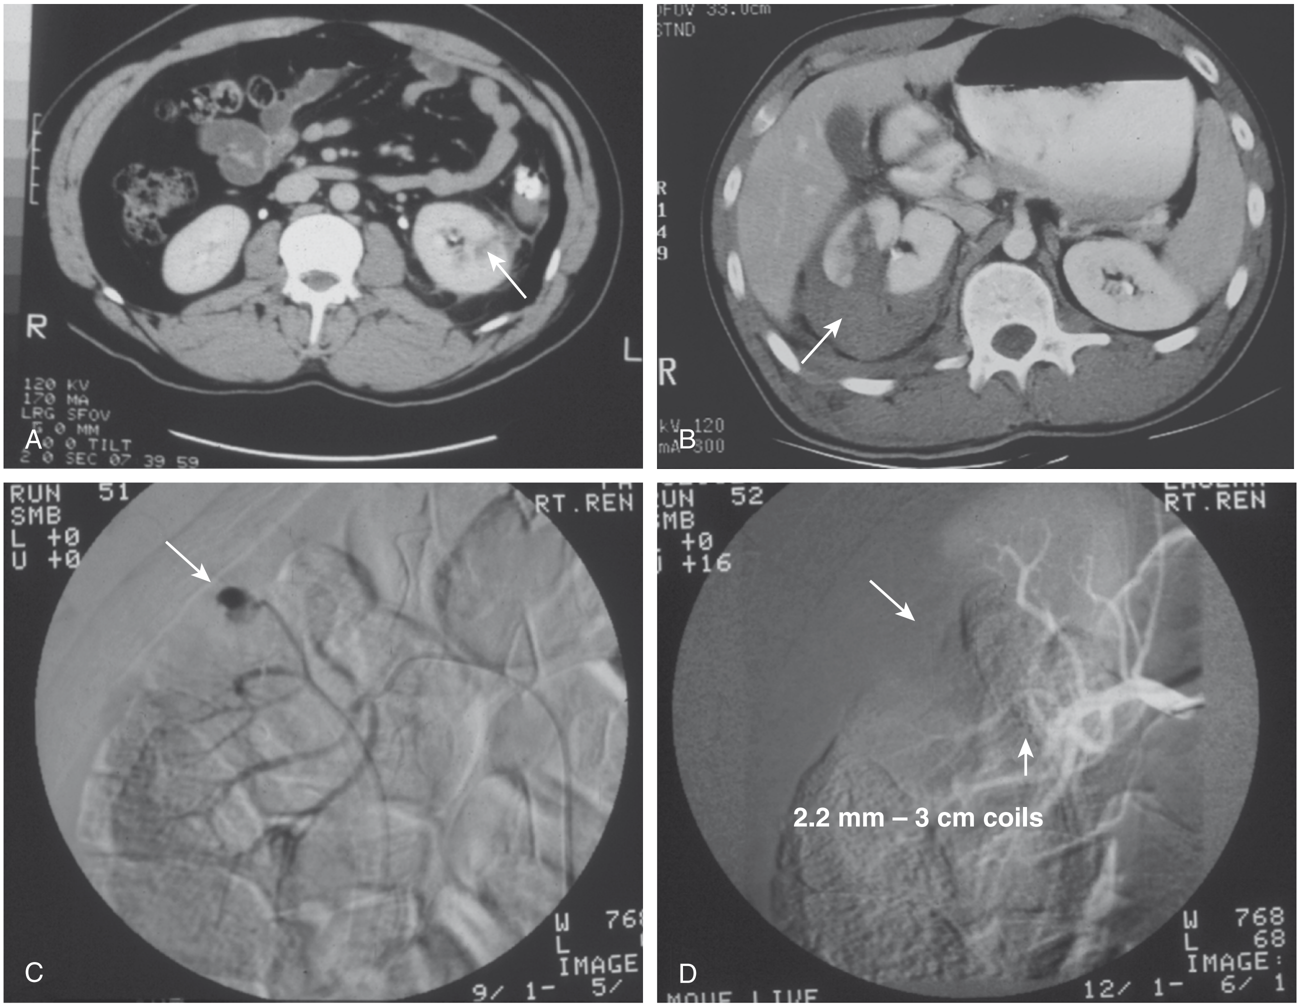

FIGURE 39.2 Penetrating renal injury on computed tomography scans. (A) Stab wound caused a superficial laceration *(arrow)* to the lateral left kidney. Small hematoma and location of posterior descending colon are notable. (B) Right kidney with deep laceration and large hematoma *(arrow)* in proximity to the renal hilum after stab injury. (C) Pseudoaneurysm *(arrow)* on renal angiography for significant hematuria and hemodynamic instability postinjury. (D) Successful embolization results in wedge-shaped defect *(arrow)* in the right kidney.

such as MRI or IVP, are not reliable in this setting. Retrograde pyelography is useful and the most sensitive radiographic test, but it is cumbersome and not a time-sensitive study in an acute setting.

Management of Ureteral Trauma

Injuries to the ureters are best managed with direct inspection and surgical repair. Specifically, when suspicion for ureteral injury remains high or in patients who have not undergone preoperative imaging, direct inspection of the ureters at time of laparotomy is critical. Intraoperative administration of methylene blue or other intravascular dye excreted in the urinary system can aid in the identification of ureteral injuries. Traumatic injuries should be repaired in hemodynamically stable patients, whereas in unstable patients, simple intraoperative tagging of the ureter with subsequent nephrostomy tube placement and delayed definitive repair can be planned. In general, nonviable tissue should be excised before reconstructing ureter. Intact ureters with minor contusion can be managed with ureteral stenting.[23] When ureteral stenting fails, patients can be managed with percutaneous nephrostomy with delayed repair.

Surgical Exploration and Operative Approach for Ureteral Trauma

Whenever possible, the injured ureter should be repaired at the same time as the initial laparotomy in stable conditions, but this may not always be possible. The ureters should be mobilized carefully, taking care to avoid stripping the adventitia to prevent further devascularization. The ureters can be debrided, albeit minimally and until bleeding edge is identified. The ureter should be spatulated and anastomosed in a tension-free fashion using fine absorbable sutures. The type of ureteral repair depends on the location of the injury. Injuries that are located proximal to the iliac vessels can be repaired primarily over a ureteral stent, and injuries distal to the iliac vessels can be reimplanted into the bladder or repaired primarily over a ureteral stent. A drain should be placed to help with postoperative management.

BLADDER TRAUMA

Approximately 1% to 2% of patients with blunt abdominal trauma have associated bladder injuries. The bladder is well insulated

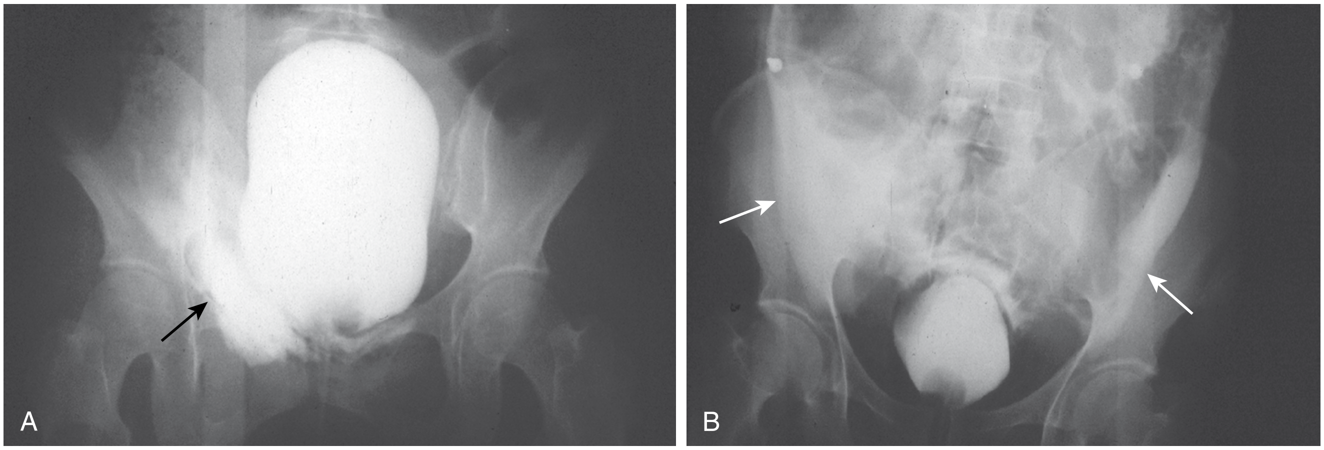

FIGURE 39.3 Cystograms in patients with gross hematuria. (A) Cystogram demonstrates extraperitoneal injury *(black arrow)*. (B) Cystogram demonstrates intraperitoneal extravasation of contrast with contrast in the colic gutters *(white arrows)* and within the peritoneum.

behind the pubic bone and within the pelvis, but significant acceleration-deceleration injuries can lead to disruption of fascial attachments, and bone fragments can directly injure the bladder. In fact, pelvic fracture is associated with 83% to 95% of bladder injuries, whereas bladder injury was associated with only 5% to 10% of pelvic fractures.[24–26] Clinical findings such as suprapubic pain or tenderness, free fluid on CT or ultrasound, low urine output, clots in urine or in bladder on CT, scrotal ecchymosis, and abdominal distention can indicate bladder injury. Nevertheless, gross hematuria is present in 75% to 100% of injuries.[25] Clinicians should have a high index of suspicion for bladder injury in patients with blunt trauma and alcohol intoxication.[27]

Imaging for Bladder Trauma

Retrograde cystography is the gold standard imaging technique to diagnose bladder injury. Given similar specificity and sensitivity, plain film or CT cystography can be performed.[28,29] Clinicians can decide on modality based on resource availability, patient stability, and ease. Antegrade distention by clamping the urethral catheter after CT with delayed imaging is not adequate for diagnosing rupture because of the lack of distention and should not be performed.[30–32] A retrograde cystography allows for (1) adequate retrograde filling with a minimum of 300 mL of contrast or until patient reaches tolerance, (2) imaging at maximal fill, and (3) imaging after bladder drainage. Retrograde cystography is important in differentiating between extraperitoneal and intraperitoneal bladder injuries. Extraperitoneal injuries are confined outside of the peritoneal cavity, whereas intraperitoneal injuries are within the peritoneal cavity (Figs. 39.3 and 39.4).

Management of Bladder Trauma

Bladder rupture does not happen as an isolated event in normal adults. Approximately 30% of patients with a bladder injury will present with gross hematuria and pelvic fracture; therefore, retrograde cystography must be performed.[33] Patients with pubic symphysis diastasis and obturator ring fracture with clinical findings suggestive of bladder injury should have retrograde cystography.[25,34]

In general, intraperitoneal bladder injuries, regardless of mechanism, should be surgically repaired. The bladder neck and ureteral orifices should be assessed for additional injuries at time of repair. Intravenous administration of indigo carmine, methylene blue, fluorescein green, or retrograde passage of a ureteral catheter can be used to assess the ureters. Extraperitoneal bladder injuries can be managed with catheter drainage for 2 to 3 weeks. Follow-up cystography should be performed to assess the injury before catheter removal. If the injury has not healed after 4 weeks of catheter drainage, open repair should be considered. There are several scenarios where immediate repair is indicated for an extraperitoneal bladder injury (Table 39.2) to reduce complications such as fistula formation, failure to heal, orthopedic hardware infection, and sepsis.[35,36]

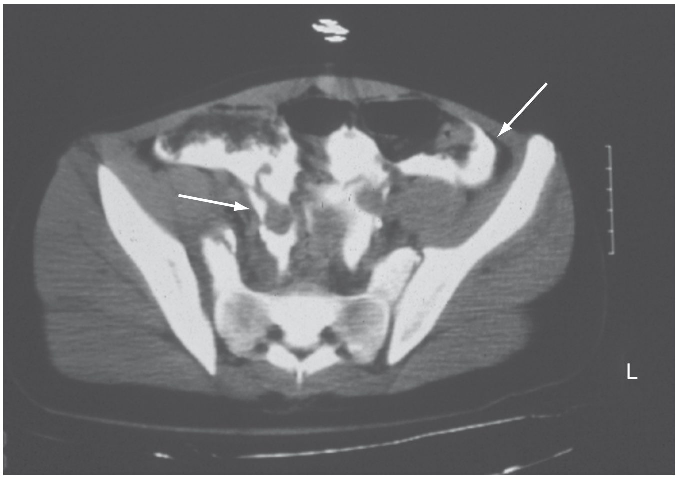

FIGURE 39.4 Computed tomography cystogram showing intraperitoneal bladder rupture. Contrast is seen in the colic gutters and around the ovaries *(arrows)*.

TABLE 39.2 **Indications for Repair of Bladder Injury**

- Intraperitoneal injury from blunt or penetrating trauma
- Inadequate bladder drainage or clots in urine
- Concomitant bladder neck, rectal or vaginal injury
- Open pelvic fracture
- Pelvic fracture requiring open reduction and internal fixation
- Bone fragments protruding into the bladder
- Stable patients that are undergoing laparotomy

Surgical Exploration and Operative Approach for Bladder Trauma

The anterior bladder wall can be identified in the midline, often by extending a laparotomy incision. Intraperitoneal injuries are often apparent and should be extended to examine the integrity of the bladder neck and ureteral orifices. The cystotomy can then be repaired in two layers using absorbable 2-0 Vicryl through 4-0 Vicryl sutures to achieve a watertight closure. Extraperitoneal injury can be closed intravesically using absorbable 2-0 Vicryl suture by entering through the anterior bladder wall. If possible, pelvic hematoma should not be disturbed. A catheter should be left to promote drainage, and a suprapubic tube is rarely needed; however, cases with complex bladder lacerations or concurrent spinal cord injury and paralysis may benefit from a suprapubic tube. If concomitant pelvic injuries are present, tissue interposition flaps should be used to separate suture lines.

URETHRAL TRAUMA

Injuries to the urethra occur in the posterior urethra (prostatic urethra, membranous urethra) or the anterior urethra (penile and bulbar urethra). Posterior urethral injuries are almost solely associated with pelvic fractures, occurring in 1.5% to 10% of pelvic fractures.[35,37] These injuries can be associated with bladder injuries 15% of the time.[38] The anterior urethra is most commonly injured at the bulbar urethra, which accounts for 85% of all urethral injuries. Blood at the meatus is present in 37% to 93% of patients with urethral injury, but patients can present with inability to void and a distended bladder.[25,33] A "butterfly" hematoma may also be present in the perineum because of rupture in Buck fascia, leading to spread of hematoma into the scrotum and along layers of the dartos and Scarpa fascia (Fig. 39.5).

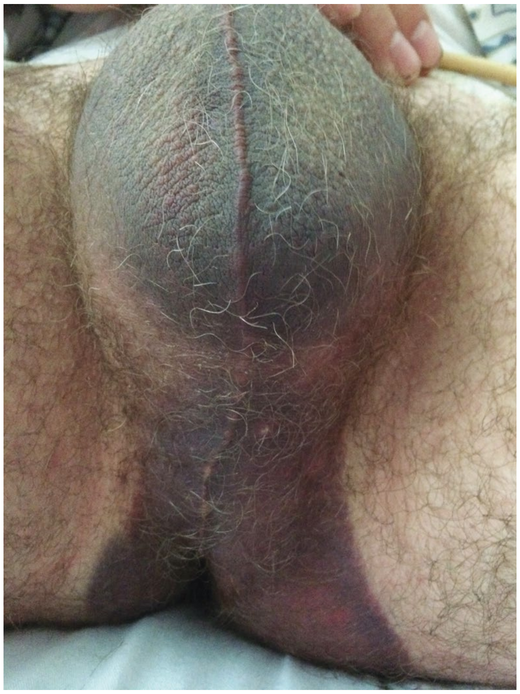

FIGURE 39.5 Rupture of Buck fascia results in butterfly hematoma after urethral injury.

Imaging for Urethral Trauma

Retrograde urethrography should be performed when blood is present at the urethral meatus after pelvic trauma (Fig. 39.6). Blind passage of a urethral catheter should be avoided. The study is performed by placing the patient obliquely on their side and filling the entire urethra with contrast such that it passes into the bladder. The penis should be placed on gentle stretch to help visualize the entire urethra. Extravasation can be visualized when contour of the urethra is lost because of partial or complete disruption. If a catheter has been placed before evaluation and urethral injury is suspected, pericatheter retrograde urethrography can be performed by injecting contrast with a 3-Fr catheter held at the urethral meatus to prevent contrast leakage.

Management of Urethral Trauma

Prompt drainage of the bladder is critical when urethral injury is present. Percutaneous or open suprapubic tube placement can provide a fast and efficient method for draining the bladder (Fig. 39.7). The placement of a suprapubic tube with delayed urethroplasty is likely superior to endoscopic primary realignment in the initial management of the ruptured posterior urethra due to pelvic fracture (see Fig. 39.7).[37] When endoscopic primary realignment is employed, prolonged attempts at realignment should be avoided because they can worsen injury severity. These patients are at a high risk of stricture formation, erectile dysfunction, and incontinence; thus, they should be followed for at least 1 year after urethral injury.[37,39–41] Straddle injuries to the bulbar urethra require prompt urinary drainage; most can be fixed primarily, although if there is extensive local tissue damage, suprapubic urinary drainage and delayed repair are preferred. Stricture formation is increased among these patients and requires follow-up surveillance with uroflowmetry, retrograde urethrogram, and/or cystoscopy. Patients with uncomplicated penetrating trauma of the anterior urethra should be repaired primarily.

Surgical Exploration and Operative Approach for Urethral Trauma

In patients who are hemodynamically stable, anterior urethral injuries caused by penetrating trauma should be explored and repaired primarily. Urethra should be examined, minimally debrided, and spatulated before primary repair. Repair should be performed over a catheter using fine absorbable suture.

Other injuries to the anterior and posterior urethra can be managed with suprapubic tube placement. If bladder is palpable and patient does not have a history of abdominal surgery, it can be placed in a percutaneous fashion. In patients with abdominal surgery, bladder ultrasound can be used to identify a safe window to place a suprapubic tube in an open fashion. A cut-down can be performed to safely identify the bladder, and a cystotomy can be created under vision. A catheter is placed in the bladder through cystostomy, and a purse-string closure is performed around the catheter. Skin closure is performed, and a suprapubic tube is secured to the skin.

GENITAL TRAUMA

Genital trauma is a diverse set of injuries caused by various mechanisms, such as blunt and penetrating injuries; amputation; bites; burns; or avulsion injuries to penis, scrotum, testicles, or vulva. As a result, the mechanism and organ that is injured should dictate how to stabilize and manage the patient. Approximately

FIGURE 39.6 Retrograde urethrogram highlights urethral patency or defects. (A) With patient in an oblique position, contrast material opacifies the anterior and posterior urethra. (B) Displaced pelvic fracture results in a posterior urethral disruption. Contrast is seen above and below the urogenital diaphragm with the bladder displaced cephalad. This demonstrates the classic "pie-in-the-sky" bladder, which is caused by a pelvic hematoma that displaces the bladder cephalad and urethra caudally.

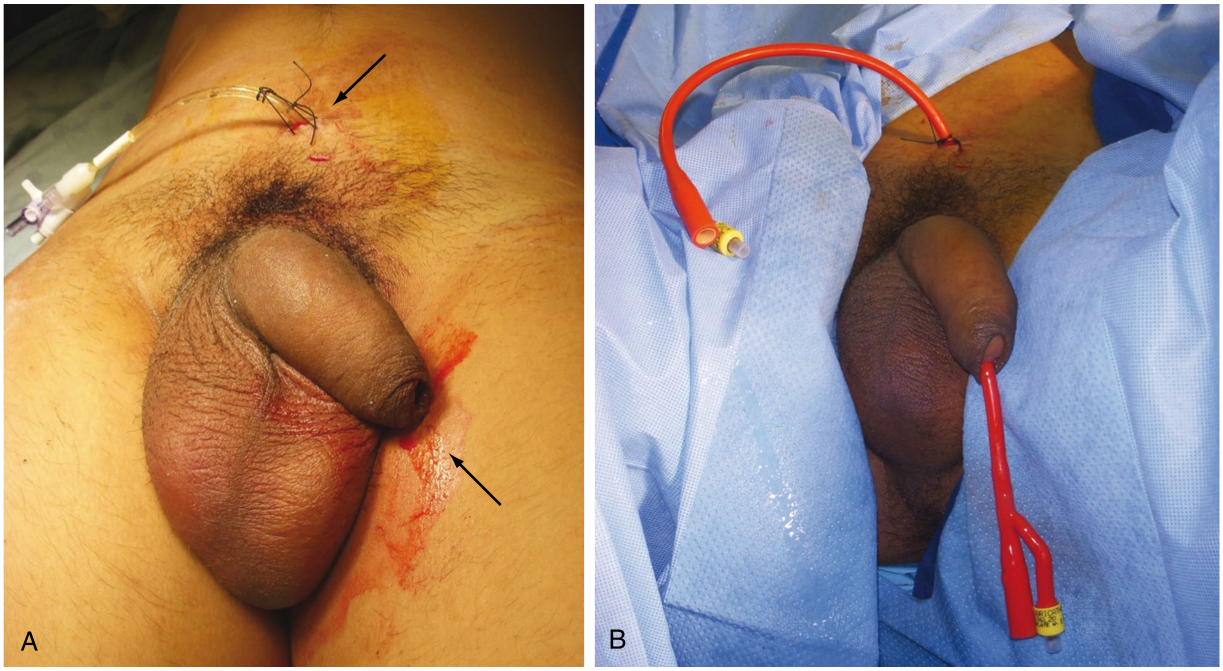

FIGURE 39.7 Posterior urethral disruption injury. (A) Blood at the urethral meatus is visible *(bottom arrow)*. Suprapubic cystotomy tube was placed percutaneously *(top arrow)*. (B) Patient underwent endoscopic re-alignment procedure with placement of urethral and suprapubic catheter.

50% to 66% of all penetrating genitourinary injuries involve the external genitalia.[42] Penetrating penile injuries can have concomitant urethral injuries in 11% to 29% of cases, and testicular rupture can be present in over 50% of cases of penetrating scrotal injuries.[42]

Imaging for Genital Trauma

With a high degree of clinical suspicion from the history and physical examination, the diagnosis can often be made without additional imaging. Penile swelling and ecchymosis are associated with penile fracture. Most often patients will report a snapping sound followed by immediate detumescence. Penile fracture can often be a clinical diagnosis; however, an equivocal sign may undergo penile ultrasound or penile MRI. Because penile fractures are associated with urethral injuries in 10% to 22% of cases, it is important to evaluate the urethra either by retrograde urethrography or cystoscopy.[43]

Scrotal ultrasonography should be performed for blunt scrotal trauma because it can accurately diagnose testicular rupture. A normal testicle will have a clear tunica albuginea surrounding the testicle, which is lost with rupture resulting in heterogenous echotexture. However, scrotal ultrasonography should not be performed with penetrating scrotal injuries, as its utility in evaluating testicular injury is limited.

Management of Genital Trauma

A thorough history and physical examination are vital for diagnosing penile fracture. Evaluating the urethra for blood and asking about urinary symptoms can help understand if the urethra is involved. Penile fractures should be promptly explored and surgically repaired to aid in faster recovery and decreased rates of penile curvature and erectile dysfunction.

For testicular injuries that require scrotal exploration, early repair of the testes is associated with increased testicular salvage and preservation of fertility and hormonal function. Additionally surrounding structures such as the spermatic cord and vas deferens can be inspected, given 7% to 9% of gunshot wounds to the scrotum injure the vas deferens.

Animal or human bites of the genitals can translocate bacteria to the wound, and therefore, copious irrigation and debridement are necessary. Immediate primary closures can be performed after animal bites with appropriate antibiotic coverage and immunization. However, human bites produce contaminated wounds that should not be closed primarily because patients often present in a delayed fashion with infected wounds.

Genital skin loss can occur from mechanical devices such as industrial machinery or from burns caused by explosive injuries. In most cases, the genitalia should be examined carefully, and healthy tissue should be preserved. Placement of a suprapubic tube early can be beneficial for wound care and avoid prolonged catheterization. Burn injuries to the genitalia should be managed like other burn injuries. Eschars should be resected early, and skin grafts should be applied when appropriate.

Surgical Exploration and Operative Approach for Genital Trauma

When penile fracture is suspected, surgical exploration should be performed regardless of equivocal imaging. Often the urethra is examined using flexible cystoscopy. Most fractures occur ventrally or laterally, and a penoscrotal incision is usually made to gain exposure over the fracture. Alternatively, an incision can be made over the area directly or a distal circumcising incision can be made to gain exposure to the corporal bodies and urethra (Fig. 39.8). Once a tunical defect is identified, a 2-0 or 3-0 absorbable suture is used to close the defect in an interrupted fashion. Debridement and ligating vessels are avoided in order to preserve erectile tissue. Similarly for penetrating trauma to the penis, the wound should be explored immediately, irrigated, any foreign body removed, and surgical closure should be performed. Urethra should also be considered to rule out any concomitant urethral injury. If a urethral injury is present, it should be closed using standard urethroplasty techniques.

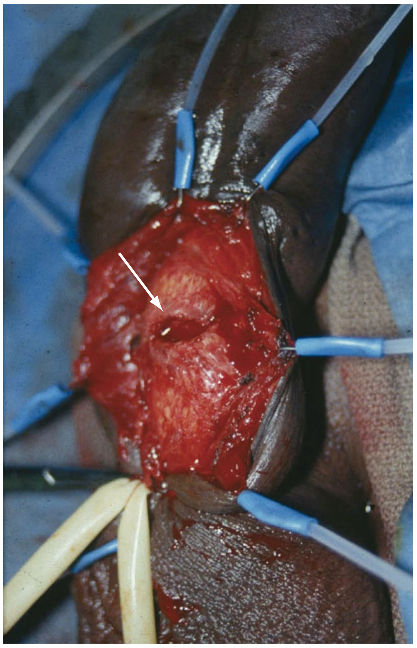

FIGURE 39.8 Surgical exploration of penile fracture demonstrates a disruption of the tunica albuginea of the corpora cavernosum *(white arrow)*. Tourniquet with a Penrose drain can help control the bleeding during repair.

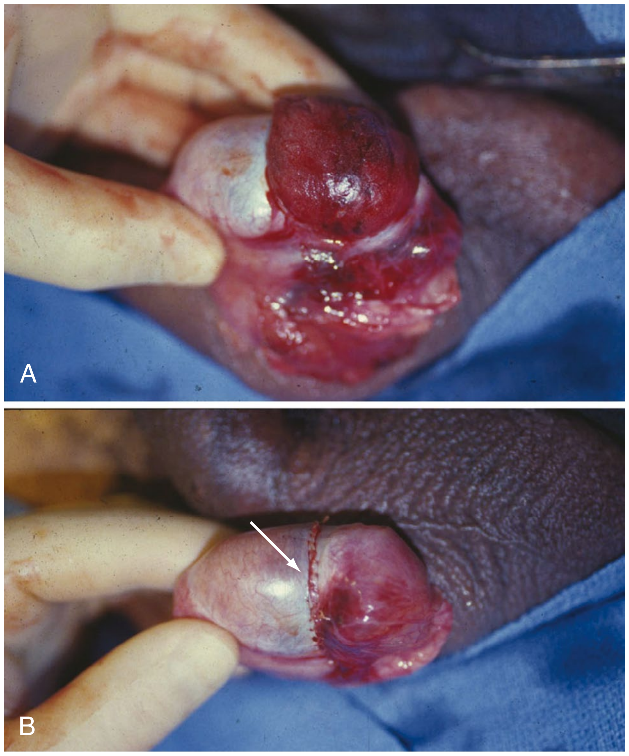

FIGURE 39.9 Scrotal exploration for testicular rupture. (A) Tunica albuginea of the testicle is disrupted with extruded testicular contents. (B) Tunica vaginalis is used to repair defect *(white arrow)*.

When testicular rupture is suspected/present or there is penetrating trauma to the scrotum, a scrotal exploration is prudent (Fig. 39.9). A transverse or vertical incision can be made on the scrotum, and the testicle should be delivered. The tunica vaginalis should be carefully dissected because it can serve as a flap to cover possible large defects in the tunica albuginea. Necrotic seminiferous tubules should be debrided, and tunica albuginea should be closed using a fine absorbable suture. Sometimes because of the degree of trauma, the testicle cannot be closed and tunica vaginalis flap can be used to cover the defect.

For patients with extensive genitalia skin loss, a split-thickness skin graft should be performed. A thick (0.012- to 0.015-inch), nonmeshed, split-thickness graft should be used for penile reconstruction. A thick, meshed, split-thickness graft should be used for scrotal reconstruction. This is most often performed in a delayed fashion. If scrotal skin is present, it can be mobilized to cover both testicles. Eventually over 6 to 12 months the neoscrotum will become more pliable and the testicles will take a more dependent position.

DAMAGE CONTROL SITUATIONS

As with any multidisciplinary surgical team, communication is a vital part of the care during traumatic injuries. Urologic injuries usually require coordinated care between the urologist, the trauma surgeon, and potentially other surgical specialists. Often when the patient is unstable, genitourinary reconstructive procedures can be deferred and temporizing measures can be taken instead. When conditions of extensive blood loss occur, significant blood and fluid replacement can occur, which can cause worsening hypothermia, acidosis, and coagulopathy. In these circumstances, only critical injuries such as severe kidney or bladder injuries should be addressed, whereas ureteral or urethral injuries can be temporized with stents or catheters, respectively. Therefore, careful patient selection is necessary when genitourinary reconstruction is undertaken.

EPIDEMIOLOGY OF ORTHOPEDIC INJURIES

Musculoskeletal (MSK) injuries are a leading cause of pain and disability and account for nearly 20% of all emergency department and primary care visits annually in the United States.[1] In 2004, MSK complaints comprised more than 57 million healthcare encounters in the United States, which represented approximately 60% of all injury treatment encounters in diverse care settings.[2] In 2006, the Centers for Disease Control and Prevention (CDC) reported that over 40 million encounters in the emergency department and primary care settings were the result of MSK complaints. Furthermore, previous authors have estimated that 8% of all emergency department encounters in the United States and Canada are due to MSK complaints,[3] whereas more recent studies have estimated it could be as high as 30% of all visits. The economic burden of MSK injuries on the healthcare system is significant and comprises both the direct costs associated with healthcare services and the indirect costs that occur due to lost work productivity. In 2014, the annual costs for medical treatment and lost wages due to MSK complaints in the United States were estimated at $980 billion, which accounted for 5.76% of the gross domestic product.[4] Patients who are 65 years of age and older are disproportionately affected compared with younger populations, and the rate is expected to continue to increase as the population ages. The utilization of the emergency department and urgent care services is also higher among older adults, with MSK complaints accounting for 31.4% of all encounters in that age group in the United States. As such, it is crucial to understand how to evaluate and identify these injuries because improper management of patients with MSK injuries can lead to poor outcomes and increased morbidity.

In the United States, it has been estimated that 46% of patients sustaining a traumatic injury have an orthopedic injury, and between 13% and 25% of these patients require an orthopedic traumatologist. At the national and global levels, substantial improvements in transportation safety and delivery of medical care have helped address this growing pandemic. Seat belt and helmet laws, enforcement of drunk driving laws, mandates for improved safety features in automobiles, rapid deployment of emergency medical teams, and establishment of trauma centers have decreased the number of accident scene fatalities. As an increasing number of patients are surviving motor vehicle collisions (MVCs) that may have been fatal in the past, emergency medicine providers and first responders will be challenged with managing more complex fractures and soft tissue wounds. These realities demand that trauma teams be aware of the frequency and consequences of MSK injuries in every trauma patient. In particular, the immediate assessment and determination of severity are of the utmost importance, as this facilitates the correct triage of patients. Furthermore, an appreciation for the unique features of skeletal injury in patients who may also have severe head, thoracic, or intraabdominal trauma is essential. In this way, a cohesive, integrated approach to the diagnosis and treatment of MSK injuries may be used in the care of the multiply injured patient.

FRACTURE BIOMECHANICS

The human skeleton provides a rigid framework for our muscles to attach, which allows for the power of movement through the contraction of those muscles on the skeleton. Movement is dependent on the integrity of the skeletal system, and if it becomes fractured or diseased, then function will become decreased. The mechanical and structural properties of bone vary throughout different locations in the body, and as a result the amount of deformation that occurs during physiologic loading and loads that cause failure differ. The strength of a particular bone is gained by the bone mineral density and the characteristics of the trabecular component (i.e., thickness and connectivity) of the bone. Also, the structure of bone affects its material characteristics and strength, and normal bone typically comes in two different forms: cortical or cancellous. Cortical bone is typically quite strong, lines the outer surface of long bones, and provides load-bearing support. Cancellous, or trabecular, bone is more porous in structure, is less strong than cortical bone, and is typically found within the metaphysis of long bones. The density of trabecular varies greatly depending on the location in the body, function, and age of the patient.

Fractures usually result when the applied load to the bone exceeds its load-bearing capacity, or when the skeleton is placed in an unaccustomed position, or is struck by an outside load. Generally, fracture patterns occur because of separate and specific types of loading, and understanding the loading pattern that caused the fracture can assist in maneuvers to reduce the fracture and/or dislocation to its reduced or nondisplaced state. Examples of these traumatic loading conditions include axial, bending, torsion, and crush, and they can also be categorized as blunt or penetrating. In the case of bending, the bone is subjected to high tensile stresses on the convex side of the bone, whereas high compressive stresses develop on the concave side. These result in a predictable fracture pattern that is composed of a transverse fracture on the tension side and a "butterfly" or "wedge" fragment found on the compressive side. The patient's age and the mechanism of injury are both strong determinants of the fracture pattern as well as the soft tissue injury that occurs simultaneously with the fracture. In the setting of an MVC, physics states that kinetic energy equals (1/2)(mass)(velocity^2), and therefore, the greater the velocity, the higher the amount of energy stored within a system. This energy is absorbed by the body and the MSK system, which results in fracture and injury to the soft tissues. Clinically, we tend to see the concept of energy as it relates to fracture mechanisms in a bimodal distribution, with young patients who have stronger bones sustaining injuries from high-energy mechanisms and elderly patients with osteoporotic bone sustaining injuries from low-energy mechanisms. This explains why high-energy mechanisms (i.e., MVC) tend to result in multiple bony and soft tissue injuries and low-energy mechanisms (i.e., ground-level fall) tend to result in isolated injuries. When bones are abnormal, whether from malignancy, infection, or a developmental defect, the mechanism may not "match" the fracture pattern, and in such cases the provider should recognize this and complete a further workup of the patient.

TERMINOLOGY

A key component of fracture care, specifically in the emergency setting, is the ability to communicate fracture characteristics effectively and concisely among providers. When initial radiographs are obtained in the emergency department, an understanding of general fracture descriptors and terminology by providers can be helpful when discussing injuries with consulting services. Fractures occur in a wide variety of anatomic locations throughout the body, involve different aspects of the bone itself, and may also be accompanied by soft tissue injuries that may or may not communicate directly with the fracture. As will be discussed later, it is important to have a general understanding of fracture terminology and the potential implications for acute treatment of various fracture types depending on their location and associated soft tissue injuries. The most practical and universally understood terminology of fractures is simply one that includes basic anatomic and mechanical descriptors, which ensures concise communication among providers. Table 40.1 includes a list of common fracture descriptors.

Fracture Types

Fractures can be classified as acute, subacute, or chronic (i.e., nonunion). Subacute and chronic fractures, although frequently needing treatment, can often be managed on an ambulatory basis and do not require emergent care. Rather, they can often be braced or splinted for comfort and treated with protected weight-bearing if indicated until further outpatient evaluation by a specialist. Radiographically, acute fractures can be differentiated from older fractures by the identification of sharp, well-defined edges of the fracture fragments and an injury mechanism to explain the injury. Subacute fractures will display evidence of callus formation and/or softening and blunting of the fracture edges and may or may not display signs of instability on physical examination. Fracture nonunions are typically at least 6 months old and radiographically can appear in a diverse variety of ways. In these cases, obtaining a detailed history from the patient will often identify the chronic nature of the injury (Fig. 40.1).

Pediatric patients experience fractures that are often different from those of adults, and this is because their bones are less dense and have increased plasticity, thicker periosteum, and open physes (Fig. 40.2). *Plastic deformity* of a long bone in a pediatric patient describes deformation of the bone without complete disruption of the cortex, and this is commonly observed in pediatric forearm fractures. The bone will show signs of angulation in one or more planes but may not have any visible fracture lines present, such as is seen with the ulna in Fig. 40.2A. In such cases, radiographs of the contralateral extremity can be quite helpful in the diagnosis by

TABLE 40.1 **Fracture Terminology and Descriptors.**

TERM	MEANING
General Terms	
Skeletal Maturity	Open versus closed physes (e.g., growth plates)
Pathologic	Fracture involving an area of abnormal bone
Insufficiency, fragility	Osteoporotic bone
Open	Fracture communicates with outside environment
Closed	Fracture does not communicate with outside environment
Children	
• Greenstick	Incomplete cortical disruption, plastic deformation
• Physeal	Involvement of the physis
• Buckle, torus	Axial crush with buckling of cortex
Location	
• Diaphysis	Shaft of long bone, thick cortical bone
• Metaphysis	Flare between the shaft and the joint surface, thin outer cortical bone
• Epiphysis	End of bone that forms joint surface
• Supracondylar	Proximal to the epicondyles (e.g., humerus and femur)
• Intercondylar	Extension between the articular condyles (e.g., humerus and femur)
• Intraarticular	Extension into the articular surface
Pattern	
• Transverse	Perpendicular to the long axis of the bone
• Oblique	Angular to the long axis of the bone
• Spiral	Torsional
• Butterfly	Separate fracture fragment at the fracture
• Comminuted	Multiple fracture fragments
Displacement	
• Translation	Percent displacement of the distal fragment relative to the proximal fragment
• Angulation	Apex volar or dorsal, apex valgus or varus
• Length	Shortened or distracted
• Rotation	Relative to the proximal fragment

confirming asymmetry between limbs. *Buckle fracture* describes an injury that occurs with axial loading of a long bone, such as a fall on an outstretched hand, leading to buckling of one or more cortices and with or without a visible fracture line. This is commonly seen in pediatric distal radius fractures (see Fig. 40.2B). *Greenstick fracture* describes an incomplete disruption of a bony cortex and usually consists of a complete cortical disruption on one side of the bone, with a buckle fracture or plastic deformation on the opposite side (see Fig. 40.2C). The dense overlying periosteum can contribute stability to many of these pediatric fracture types if the layer remains intact, which is why many are treated successfully with closed reduction and splinting. Not uncommonly, a pediatric patient will present with pain or refusal to use an extremity, yet radiographs will appear normal. In those cases, radiographs of the contralateral extremity can be obtained to assess for deformity; however, care must also be taken to not miss an injury to nonossified, cartilaginous physis (i.e., growth plate). *Physeal fractures* are unique to pediatric patients and may present in six different types, as described by the Salter-Harris classification system (Fig. 40.3A). The physis of a bone is typically located at the ends of bones at the metaphyseal-epiphyseal junction, represent the center of longitudinal bony growth, and ossify at different points throughout a child's life. Fracture through or disruption of one of these "ossification centers" can alter the future growth of the affected bone, leading to length discrepancies and/or angular deformities. Especially in younger patients whose skeleton is largely not ossified, these injuries can be difficult to diagnose, and therefore, providers should maintain a high level of clinical suspicion when radiographs appear normal.

When a bone fails through an area weakened by preexisting disease, it is termed a *pathologic fracture*. Common causes of this may include weakness from primary bone tumors, metastatic lesions, infection, metabolic disease, skeletal dysplasia, and injury through an old fracture site. Although they are not commonly referred to in this way, fractures in osteoporotic bone may be considered pathologic. The term *insufficiency* or *fragility fracture* is more commonly used to describe these injuries. In contradistinction to acute fractures in healthy bone, fragility fractures result from an injury mechanism with much lower energy, such as a fall from standing height. Hip fractures, distal radius fractures, and compression fractures of the vertebral bodies in older adults are common examples. When diagnosed, in addition to providing appropriate acute treatment of these injuries, it is also important to ensure these patients receive a referral to a bone health specialist for further evaluation and treatment to help prevent future fragility fractures.

A fracture is considered *open* when an open wound communicates with the fracture site, which may often display evidence of fracture hematoma draining through the wound. Wounds that communicate with the fracture may not always directly overly the fracture site, and therefore, a thorough physical examination and inspection of the wound are critical in the diagnosis. It is extremely important that open fractures are not missed because their presence has implications for immediate treatment in the emergency department (i.e., prophylactic antibiotics), treatment in the operating room, and the long-term outcomes. Open fractures present on a spectrum, ranging from small (<1 cm, "poke-hole") wounds to severe soft tissue wounds with extensive stripping and degloving of the underlying tissues. The Gustilo-Anderson classification is most widely used to classify the open fractures. In practice, it can be dichotomized into *high energy* and *low energy* injuries, leading to a more consistent determination of treatment. High-energy fracture patterns indicate that the soft tissues and the bones have experienced a much greater degree of energy and forces. Although a skin laceration may be the most evident component found on physical examination, the energy of the fracture, degree of contamination, and soft tissue injury must all be taken into account in evaluating the severity of the injury. For example, a highly comminuted distal femur fracture with a 10-cm open wound after a high-speed MVC would most appropriately be classified as a type III open fracture because of extensive soft tissue damage that often occurs in these fractures. This communicates the severity of injury to the surgical team and also initiates appropriate antibiotic prophylaxis in the emergency department. Finally, the true classification of open fractures occurs only in the operating room, after thorough debridement and evaluation of the soft tissue envelope.

A fracture that extends into a joint is termed *intraarticular*. These injuries may result from an axial load across the joint (i.e., tibia plateau or tibia plafond fractures) or from a variety of other mechanisms. The articular surface must remain congruent to ensure proper function and articulation, so displaced intraarticular fractures generally require open anatomic reduction to restore the

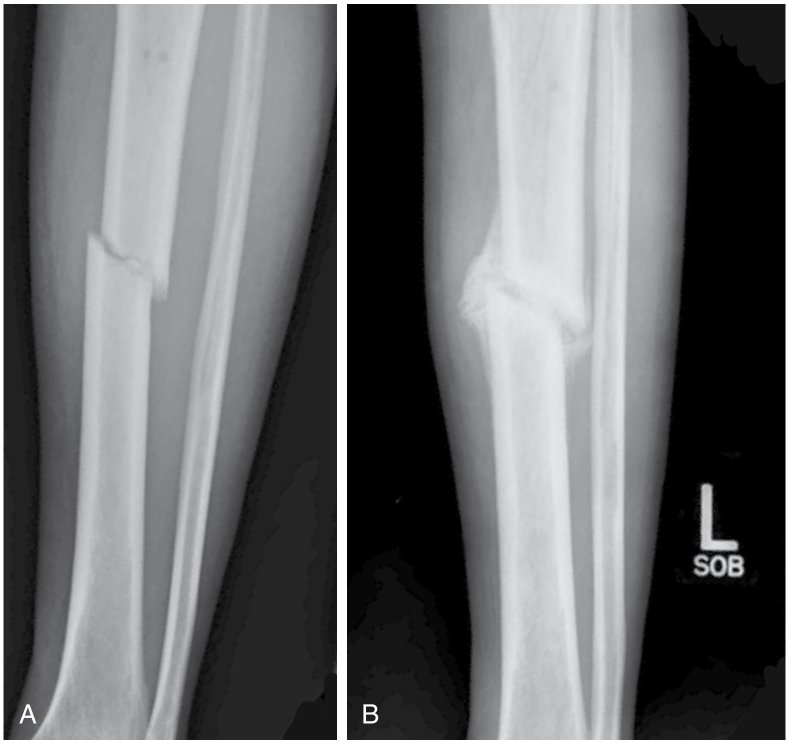

FIGURE 40.1 (A) Acute fracture. Note the sharp, well-defined edges. (B) Nonunion. Six months later, the fracture line is still clearly visible, the edges of this fracture are blunted, and the bone ends are sclerotic with callus formation. There was still motion at the fracture site on clinical examination, and the patient had significant chronic pain.

articular surface and are stabilized with rigid internal fixation to minimize the risk of posttraumatic arthritis. This is distinctly different from a fracture of the diaphysis (shaft) of a long bone, such as the femur, which can be treated with a closed reduction to restore length, alignment, and rotation. If the bone heals imperfectly from a radiographic appearance but the mechanical axis has been restored, the patient will likely experience a good outcome.

Long bone fractures are characterized by the anatomic location of the fracture (see Fig. 40.3B). The epiphysis comprises the area between the physis, or physeal scar, and articular surface. The metaphysis is located between the epiphysis and diaphysis and includes the growth plate. The diaphysis encompasses the shaft of the bone between the proximal and distal metaphyses. The diaphysis is composed of dense cortical bone that surrounds a medullary canal, and the metaphysis generally has thinner cortical bone that surrounds a core of cancellous bone. The diaphysis has relatively less vascularity than the soft cancellous bone of the metaphysis, and this difference in vascularity affects the rate at which the bone heals. Long bone fractures can also be described according to their location along the bone—proximal, middle, or distal third, and this classification is known as the *AO/OTA (Arbeitsgemeinschaft für Osteosynthesefragen/Orthopedic Trauma Association) Classification scheme.* Because long bones are important for movement and have several soft tissue attachments, such as those from muscles and tendons, fracture displacement is often a product of the deforming forces from those soft tissue attachments, and knowledge of their insertions can aid in achieving a successful reduction.

Metaphyseal fractures of the distal humerus and femur are referred to as *supracondylar* and may or may not be accompanied by intercondylar extension if there is involvement of the articular surface. The condyles are the medial and lateral bony prominences to which the stabilizing ligaments and muscles of the elbow and knee are attached. Presence of articular surface involvement, such as an intercondylar distal humerus fracture, is an important distinction to make when considering treatment because, as stated earlier, the articular surface requires an anatomic reduction to restore joint congruity.

After properly identifying the location of a fracture, the actual fracture pattern should be described (Fig. 40.4). The orientation of the primary fracture line may be transverse, oblique, or spiral. Bones are generally weakest in torsion, and spiral fractures result from torsional forces. Transverse and oblique patterns result from forces that occur perpendicularly or at an angle to the anatomic axis of the bone. However, there is often a combination of these forces, which results in a pattern that is a summation of the forces. Fracture comminution can occur in the form of a wedge or "butterfly" fragment. When a bending moment is applied to a bone, the concave side experiences a compressive force while the reciprocal convex side experiences a tensile force. Bone initially fails on the tension side, and as the fracture propagates toward the concave side, the fracture exits proximal and distal to compressed bone, creating a wedge-shaped fragment, or "butterfly." *Comminution* refers to the presence of multiple fragments within an individual fracture site and usually indicates a higher-energy injury or weakened bone in an older patient. Segmental patterns are composed of fractures at multiple locations along the same bone, with at least one intercalary segment of bone that is intact between the fractures. These also represent a higher-energy fracture pattern.

Displacement, if present, is described through a combination of principles. Deformities may occur in any plane,

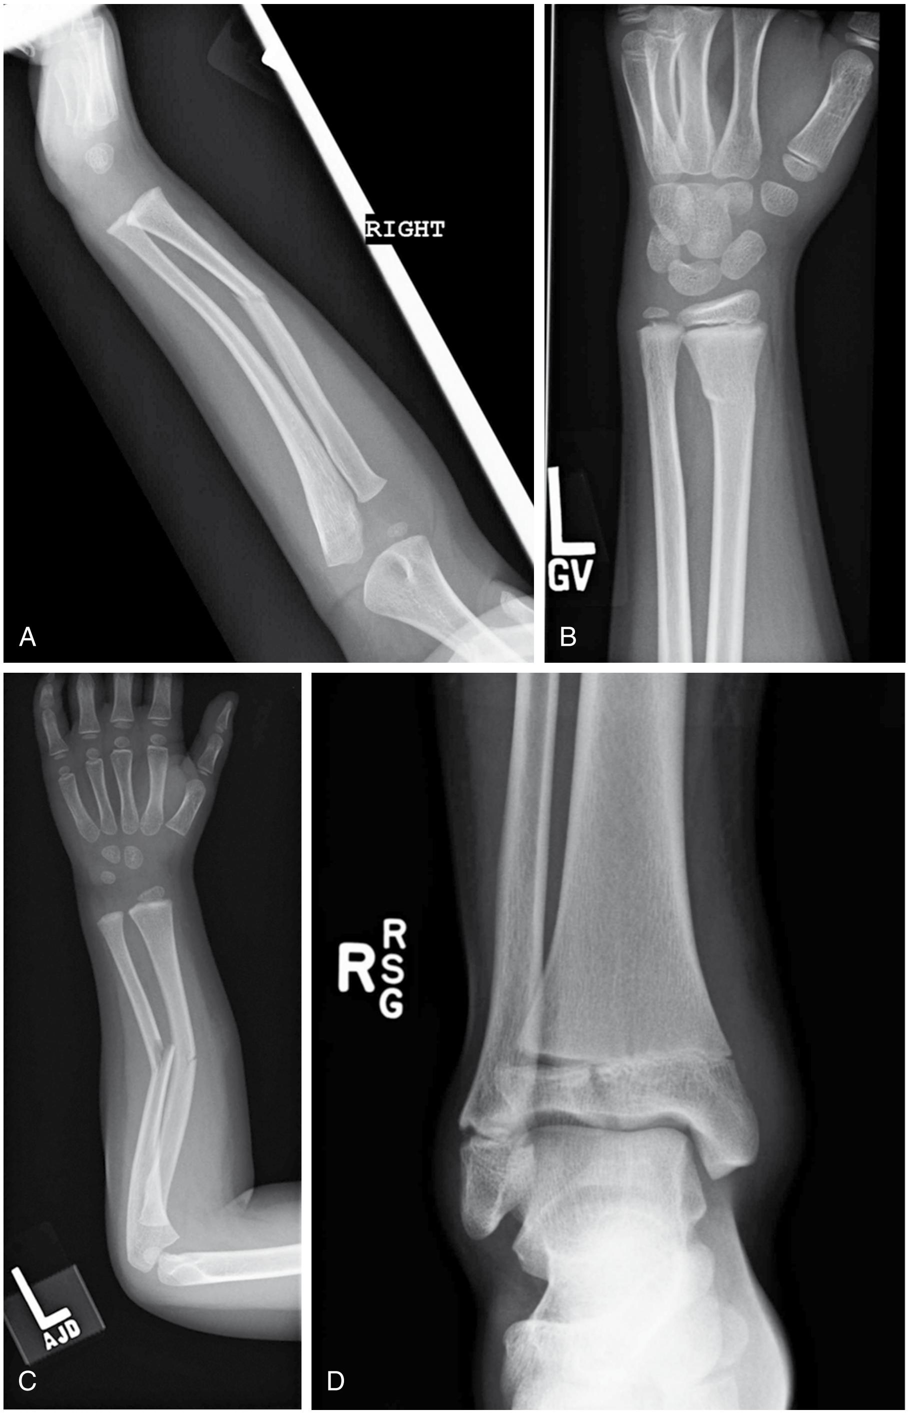

FIGURE 40.2 (A) Plastic deformity. Note the bowing of the ulna. (B) Buckle fracture. The cortex of the distal radius is deformed but intact. (C) Greenstick fracture. Disruption of radial cortices, without disruption of the ulnar cortices, in this forearm fracture in both bones. (D) Physeal fracture. Note the gapping of the lateral tibial physis.

including the coronal, sagittal, and axial planes. When viewed on plain orthogonal radiographs, fractures can be described by their coronal or sagittal displacement. However, the true displacement is a summation of all three planes. As such, fractures can be further described by their degree of translation, angulation, rotation, and shortening. Translation is the relationship of the distal fracture fragment to the proximal segment and is described in units of length (i.e., centimeters) or a percentage of the bone's width at that level. Angulation is simply the angle created by the two ends of the fracture and is conventionally described in two ways. The first is by the direction of displacement of the distal segment relative to the proximal segment, and the second is by the direction of the apex of the fracture. For example, the fracture shown in Fig. 40.5 may be described as dorsal angulation of the articular surface or apex volar angulation at the fracture site.

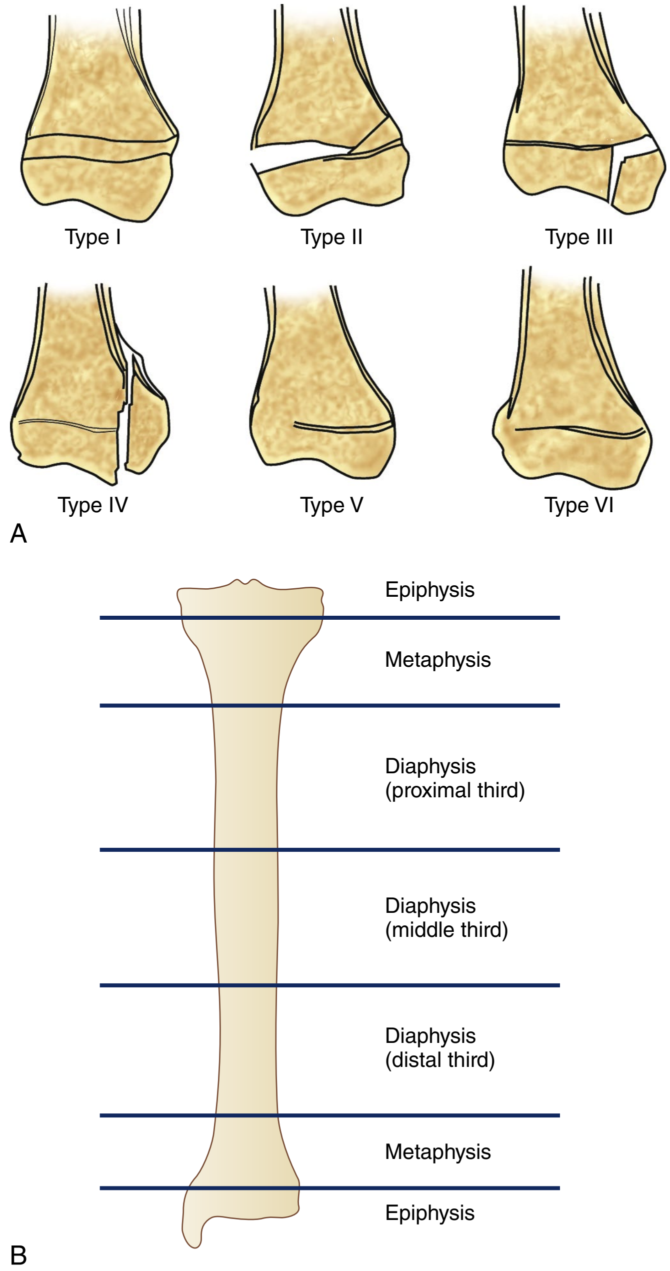

FIGURE 40.3 (A) Salter-Harris classification of growth plate injuries. (B) Anatomic regions of the tibia. (From Janicki JA. Salter-Harris fractures. In: Miller M, Hart JF, MacNight JM, eds. *Essential Orthopaedics*. Saunders Elsevier; 2010;939-943.)

Rotational deformity can be difficult to determine on radiographs, and full-length films of the limb segment involved, including the joints above and below, must be imaged to determine rotation. Advanced imaging, such as a computed tomography (CT) scan, viewed in the axial plane can also give information on rotation. Alternatively, rotational deformity may be assessed clinically by comparing the injured limb with the contralateral side.

Once a fracture has been identified, it must be described in a consistent, systematic manner. All descriptions begin with whether the fracture is open or closed, and if open, the degree of soft tissue injury must be communicated. Next, fracture laterality, location of the fracture along the bone involved, and fracture pattern are stated. The presence of intraarticular extension, if visible, should be noted. Then the general displacement pattern of the fracture can be described. Finally, it is also important to indicate any associated nonorthopedic injuries that may alter the timing of any planned initial orthopedic management. Adherence to this scheme allows for comprehensive and concise communication of the fracture characteristics.

Other Injuries

Ligamentous injuries are commonly encountered in association with traumatic injuries to bones and joints. When a ligament attached to a joint is damaged but is still in continuity, it is termed a *sprain* and can range in severity from minor injuries to significant instability about the joint. Grade I ligamentous injuries are caused by stretching of a ligament or ligament complex without causing instability, and an example of this would be a simple ankle sprain. Grade II ligamentous injuries are caused by partial ruptures of ligaments and can result in minor instability. Complete ruptures, or grade III ligamentous injuries, result in significant instability of the associated joint and are commonly seen in the setting of multiligamentous injuries after a knee dislocation. Another example of a grade III injury is an avulsion fracture, which can occur when the insertion of a ligamentous structure completely avulses from its bony insertion, resulting in instability. Ligamentous injuries should not be overlooked when evaluating patients with MSK injuries because they can lead to significant joint instability, which endangers the cartilage surface and surrounding soft tissue and neurovascular structures. As such, a full neurovascular examination should be performed whenever there is suspicion of joint instability or dislocation. Although many ligamentous injuries do not require urgent orthopedic management, stabilization or immobilization of the joint with a splint or brace is usually recommended to prevent further injury.

In contrast, a *strain* describes an injury to a muscle or tendon that is not attached to a joint, and therefore does not as commonly result in joint instability. Like sprains (noted earlier), strains range from mild to severe and commonly are the result of an overuse injury pattern. In the setting of injury, further loading of the already weakened tendon or muscle can worsen the injury and lead to partial or complete rupture. Rest, ice, compression, and elevation (RICE) are the mainstays of treatment for a muscle or tendon strain; however, more urgent orthopedic evaluation and management are indicated in the setting of rupture. Tendon ruptures can be treated nonoperatively in some cases, and therefore, proper positioning and immobilization of the joint are important to ensure that the tendon scars down in a functional position. If operative management is indicated, prompt evaluation by an orthopedic provider should occur to direct further treatment and prevent scarring of the tendon and contracture of the muscle that may complicate the operative reparative or reconstructive procedure.

Joint injuries without fracture such as articular contusions or bone bruises are common in axial loading mechanisms and may present with significant pain and inability to bear weight. Treatment is typically nonoperative with a period of rest and protected weight-bearing; however, cartilaginous injury from the axial load can lead to late degenerative changes in the joint. An osteochondral fracture or defect can result when a piece of articular cartilage and its underlying subchondral bone become separated from the surrounding joint surface. Small osteochondral defects can be asymptomatic, but, in other cases, the patient

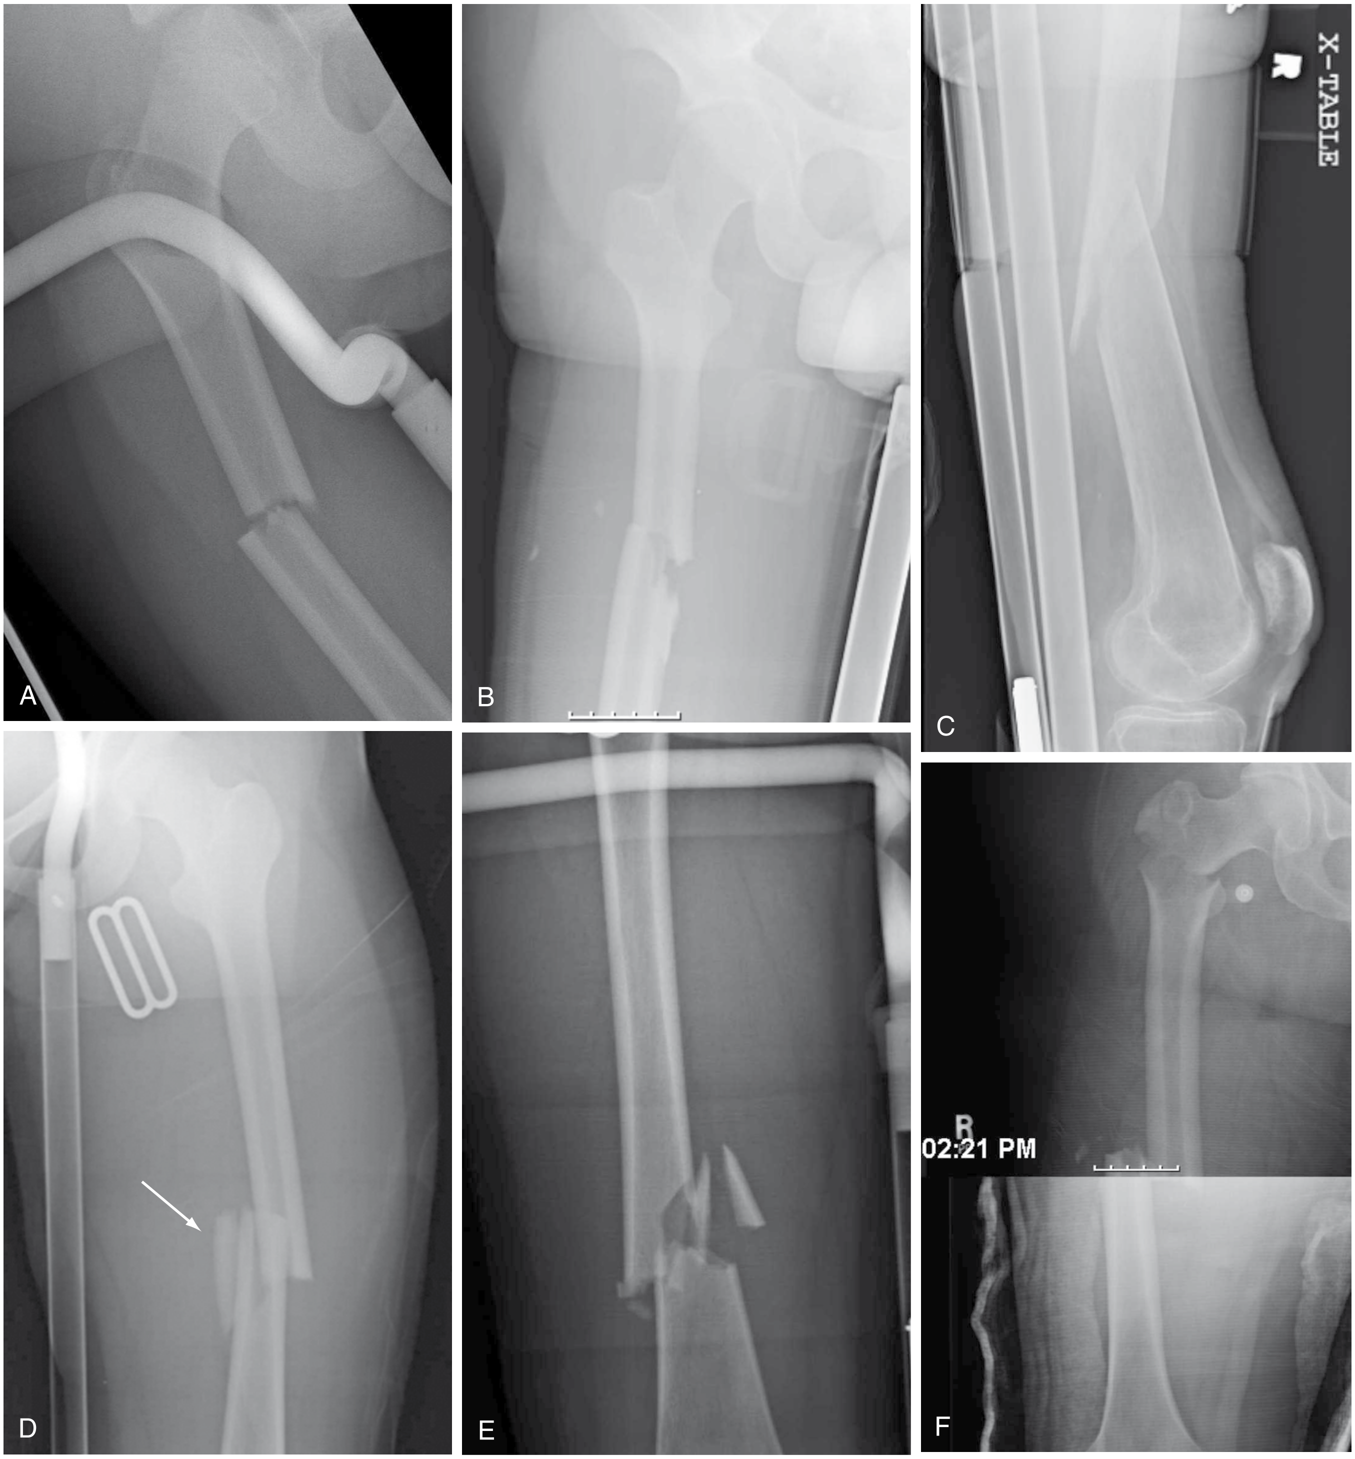

FIGURE 40.4 Femur fracture patterns. (A) Transverse. (B) Oblique. (C) Spiral. (D) Butterfly fragment *(arrow)*. (E) Comminuted. (F) Segmental.

may report mechanical symptoms such as locking/catching with joint range of motion. If missed during evaluation, these injuries can lead to chronic pain and joint degeneration. In some injuries, the osteochondral fragment will be large enough to be diagnosed on plain radiographs. When recognized, it is important to immobilize the joint to minimize further joint injury from the fragment and direct further evaluation to an orthopedic provider. Other commonly injured joints are the intervertebral discs in the spine. These discs are made up of a viscoelastic nucleus pulposus surrounded by a dense, fibrous anulus fibrosus. With a large enough axial load, the nucleus pulposus can herniate through the anulus, resulting in a disc herniation. This disc bulge can impinge on nerve roots, causing back and radicular pain, and most often these injuries do not require acute intervention. Very rarely, severe disc bulge in the lumbar spine can cause significant impingement on the cauda equina, resulting in cauda equina syndrome. This is a surgical emergency and is discussed in more detail later in the chapter.

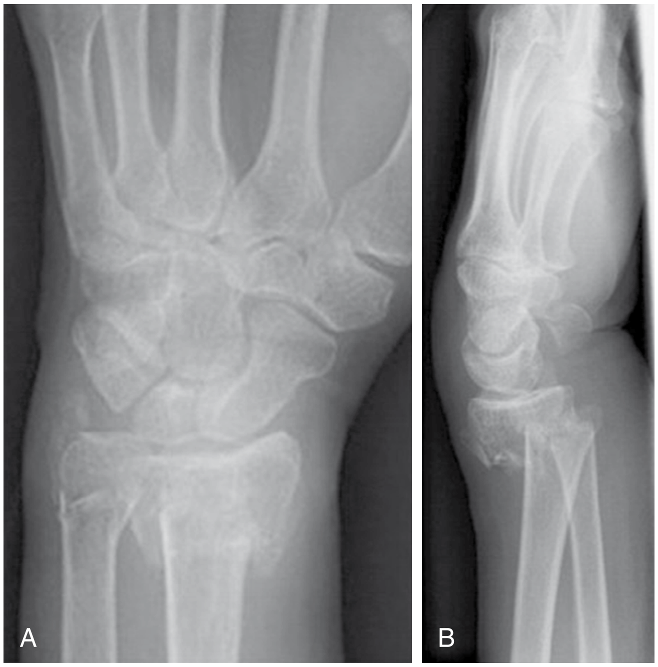

FIGURE 40.5 Posteroanterior (A) and lateral (B) left wrist radiographs of a 75-year-old patient who fell and sustained a dorsally translated, apex volar angulated, distal radius fracture and a comminuted displaced distal ulna fracture. (From Foster B, Bindra R. Intrafocal pin plate fixation of distal ulna fractures associated with distal radius fractures. *J Hand Surg.* 2012;137:356-350.)

FRACTURE STABILIZATION AND FIXATION

In the emergency setting, there are several ways to stabilize an injured extremity, varying in how effective they are in stabilizing the fracture and/or joint. Table 40.2 summarizes the methods of temporary stabilization that can be used in the emergency department as well as more invasive methods of both temporary and definitive fracture fixation. Each method has clinical situations in which it is indicated, and those general indications are outlined in the table. The methods are arranged in order of increasing ability to stabilize the fracture and/or joint. For completeness, several techniques for fracture fixation are listed within the table; however, further discussion of the principles of fixation and implant application fall outside the scope of this chapter.

There are a couple important concepts to discuss when considering each of these methods. First, is the bone being directly or indirectly controlled? Splinting (plaster/fiberglass/boot or traction splint) is the most common and least invasive form of limb stabilization. Splints are commonly applied in the emergency department setting and do not directly contact the bone. As a result, their ability to stabilize a fracture and/or joint is less effective. Skeletal traction, and in some institutions external fixation and closed reduction with percutaneous pinning (CRPP), may be applied in the emergency department under light sedation or local anesthesia. These modalities of stabilization directly involve the bone, which can improve stabilization of the fracture/joint; however, because of their invasive nature, they do have an inherent risk of infection. The closer an implant can be applied to the bone, the more effective it will be at stabilization. As an example, splints placed on morbidly obese patients are less effective than those on thinner patients because of the thicker soft tissue envelope between the splint material and the bone. As a result of this principle, application of a plate on the surface of the bone or insertion of an intramedullary nail within the medullary canal are far more effective at stabilization than any of the other techniques listed in the table.

Second, one must always consider infection risk when deciding on treatment, whether it be temporizing or definitive. Skeletal traction, percutaneous pins, and all forms of external fixation

TABLE 40.2 Methods of Skeletal Stabilization and Fixation

METHOD	DETAILS	COMMON INDICATIONS	PROS	CONS
Splinting	Plaster, fiberglass, fracture boot	Temporary stabilization of acute extremity injuries	Accommodates soft tissue swelling	Indirect control of the bone; not length stable
Traction splint	Commercially produced device	Temporary stabilization of femoral shaft fractures	Helps control pain and bleeding; maintains length	Indirect control of the bone; may produce pressure ulcers at the ischial tuberosity and ankle
Skeletal traction	Transosseous pin, traction bow, and weight	Temporary stabilization of femur and pelvis fractures	Helps control pain and bleeding; maintains length	Indirect control of the bone; does not allow for patient mobilization
External fixation (pins/bars)	Multiple transosseous pins with attached external bars	Temporary stabilization of acute extremity injuries	Improved control of the bones and thus improved soft tissue control; length stable	May allow too much motion for most fractures to heal
Closed reduction and percutaneous pins (CRPP)	Transosseous pins across a fracture site	Small bone fixation; pediatric fixation	Limited soft tissue disruption; removed once fracture healed	Risk of pin-site infection; indirect reduction of fracture
External fixation (pins/wires, rings)	Multiple transosseous pins/wires with attached external rings	Definitive fixation with the ability to manipulate the bones	Can be used for complex deformity correction and fractures	Risk of pin-site infection; indirect reduction of fracture
Intramedullary nailing (IMN)	Nail placed within the medullary canal of the bone	Long bone fracture treatment	Limited soft tissue disruption; relative stability	Indirect reduction of fracture; limited utility in treating articular fractures
Open reduction and internal fixation (ORIF)	Plates and screws	Articular fractures; upper extremity long bone fractures; ankle fractures	Direct anatomic reduction and absolute stability	Larger soft tissue disruption; biomechanically less strong than nails because of location of implant relative to mechanical axis

involve placement of an implant that communicates between the bone and the outside environment. This does carry a risk of infection; however, pin-site infections are common and often respond well to pin-site care and oral antibiotics. In the event of a more severe pin-site infection, removal of the pin or wire usually facilitates eradication of the infection.

Finally, does the surgeon have direct visualization of the fracture? Apart from displaced intraarticular fractures or fracture dislocations, not all other fractures necessarily require an open anatomic reduction. An important risk of the surgical exposure, fracture cleaning, and reduction to keep in mind is the stripping of the soft tissue attachments from the bone. This leads to decreased vascularity at the fracture site, increasing the risk of delayed or nonunion and possibly infection. When considering fixation of long bones, fractures in specific bones such as the radial shaft may benefit more from open reduction and internal fixation, whereas a femoral shaft fracture can be treated with an intramedullary nail through closed reduction and no direct visualization of the fracture site; in this case, the primary objective of the surgery is to restore length, alignment, and rotation of the mechanical axis. Overall, each method of fracture stabilization and fixation has its own set of indications and advantages and disadvantages. The choice of the most appropriate method of fracture stabilization (whether it is temporary or definitive) depends on the clinical situation, the resources available, and the surgeon's capabilities.

PATIENT EVALUATION

History

Obtaining a detailed history from patients with MSK injuries is essential for accurate diagnosis and treatment. At times this can be quite challenging depending on the clinical status of the patient. It is not uncommon for trauma patients to arrive intubated, intoxicated, or delirious. In these cases, an account of the mechanism of injury and patient history should be obtained from family members, emergency medical response crew members, or other witnesses to the accident. Descriptions from the injury scene can be helpful when deciding on acute treatment because common injury patterns often occur from specific mechanisms (Table 40.3).

A general history that includes demographic information, past medical history, past surgical history, and social history should be obtained. Knowledge of allergies, current medications, and time since last oral intake is important in guiding treatment. Each patient should be kept from eating or drinking anything until a full evaluation is performed by all pertinent services. Information about the position of the limb before and after the injury and the direction of the deforming force can help predict injuries and potentially associated injuries. Ambulatory status before the injury helps determine realistic goals for functional recovery, and it can also drive treatment decisions. For example, if an elderly patient presents with a femoral neck fracture, it is helpful to know if they previously ambulated in the community or primarily within their household because it may indicate one surgery over another. Any transient neurologic symptoms, such as loss of consciousness, numbness, dysesthesias, and spasm, must be documented. Loss of bowel or bladder control in patients with back or neck pain must also be noted. Finally, the time elapsed since injury becomes critical information in patients with an ischemic limb secondary to a vascular injury, an open wound with gross contamination, or a joint dislocation.

TABLE 40.3 **Common Injury Mechanisms and Associated Injuries**

INJURY PATTERN OR MECHANISM	ASSOCIATED INJURIES
Fall from a height	• Calcaneus fracture • Tibia plateau fracture • Tibia plafond fracture • Fractures around the hip (proximal femur, acetabulum) • Pelvic ring or sacral fracture, including vertical shear injuries • Vertebral body fracture

Fall onto outstretched hand	• Distal radius fracture
	• Elbow dislocation
	• Pediatric
	  • Both-bone forearm fracture
	  • Supracondylar humerus fracture

Fall onto shoulder	• Clavicle fracture • Acromioclavicular (AC) joint separation • Proximal humerus fracture
Ejection from vehicle	• Closed head injury • Spine fracture
T-bone motor vehicle crash	• Lateral compression–type pelvic ring injury • Closed head injury • Thoracic injury

Head-on motor vehicle crash	• Abdominal visceral injury
	• Retroperitoneal bleeding
	• Injuries caused by floor board intrusion
	  • Calcaneus fracture
	  • Tibia plateau fracture
	  • Posterior hip dislocation

Motorcycle crash	• Anterior-posterior compression-type pelvic ring injury • Mangled limb
Posterior knee dislocation	• Popliteal artery or vein injury • Common peroneal nerve injury • Multiligamentous knee injury
Supracondylar humerus fracture	• Brachial artery injury • Nerve injury (median or radial)
Anterior shoulder dislocation	• Axillary nerve injury
Posterior hip dislocation	• Sciatic (peroneal division) nerve injury • Posterior wall acetabulum fracture

Trauma Evaluation

Although beyond the scope of this chapter, examination of a multiply injured patient must adhere to Advanced Trauma Life Support (ATLS) protocols in a systematic fashion and must be accompanied by appropriate treatment. The concept of life before limb dictates the rapid initial evaluation of the injured patient. Hemodynamically unstable patients are assumed to be in hemorrhagic shock until proven otherwise. Historically, there has been debate about whether the anteroposterior (AP) pelvis radiograph, which has traditionally been considered part of the standard trauma radiographic series, is justified with the advent of newer CT scanners. However, many interdisciplinary trauma programs still obtain an AP pelvis radiograph at the time of the initial survey, especially for those in hemorrhagic shock, because it can be done quickly and will provide immediate information regarding the presence of a hip dislocation, acetabulum fracture, or pelvic ring injury. Additionally, it will serve as a baseline radiograph for comparison before any acute intervention that is provided, such as reduction of a hip dislocation or application of a pelvic binder in a patient with a volume-expanding pelvic ring injury. It is essential that if an institution enacts a protocol that skips the AP pelvis x-ray in favor of CT that the patient is expedited to intravenous contrasted CT in a timely fashion so that these potentially life-threatening findings are not missed.

In the initial care of MSK injuries, open fractures, those with vascular injury or compromise, or those developing compartment syndrome take precedence over lesser MSK diagnoses. In the setting of an open fracture, one of the most important treatment decisions a provider can make is prompt administration of appropriate prophylactic antibiotics and tetanus prophylaxis as soon as possible. Delayed administration of antibiotic prophylaxis has been shown in multiple studies to markedly increase the risk of infection.[5,6] In a recent review of 276 recommendations with regard to systemic antibiotic administration, all authors recommended administration within 3 hours of injury, and half of those recommended administration immediately after injury and/or on presentation to the emergency department.[5] Authors generally recommend coverage for gram-positive bacteria (i.e., cefazolin) in type I and II injuries and the addition of gram-negative and organic material contamination coverage (i.e., vancomycin) in more severe type III injuries.[5,6] When possible, providers should also consider an initial splinting and sterile dressing wound coverage in the emergency department to bridge the patient reaching an orthopedic assessment and ultimately the operating room.

Generally, examination and management of the extremities are deferred to the secondary survey after the airway has been controlled and hemodynamic stability has been obtained, especially because open extremity wounds can be distracting to the team. One caveat is the conscious patient who is able to follow commands but will need intubation to protect the airway. In this case, a quick neurologic examination of the extremity motor and sensory function can be performed before sedation or intubation, which provides valuable information and takes only seconds to carry out.

Unstable pelvic fractures are typically addressed in the primary survey, and stabilization with a pelvic binder/sheet in volume-expanding injury patterns can limit further hemodynamic deterioration. Evidence of large flank or buttock contusions and swelling may also indicate underlying pelvic bleeding or more superficial soft tissue injuries. A Morel-Lavallée lesion is commonly present in patients with pelvic or lower extremity trauma and represents a subcutaneous degloving injury from the underlying muscle and fascia. Blood at the urethral meatus, signifying injury to the genitourinary tract, may be a sign of an underlying pelvic fracture as well. Palpation of the symphysis pubis can help determine the presence of disruption of this joint; however, this will generally be discovered on the AP pelvis radiograph or CT scan. Gentle lateral compression through the iliac crests can assess for instability of the pelvic ring. Rectal and vaginal examinations are performed, noting the presence of gross blood, lacerations, bone fragments, hematomas, or masses. Wounds and palpable bone fragments found on either of these examinations are diagnostic of an open pelvic fracture and should be promptly treated as such. Rectal examination can also reveal a high-riding prostate gland (i.e., longer distance from the anal verge or nonpalpable), which is another suggestion of injury to the genitourinary tract after a pelvic fracture.

Examination of the extremities in either a patient with an isolated injury or a multiply injured patient should follow a simple, systematic, and reproducible algorithm. Even when an isolated extremity injury is the primary reason for evaluation, the entire skeleton must be examined. The examiner must not be distracted by other obvious or more severe injuries. Deformity, edema, ecchymosis, crepitus, tenderness, and pain with motion are the cardinal signs of an acute fracture or joint injury. Each aspect of each extremity needs to be examined for lacerations and the signs of trauma described earlier. All joints are put through passive range of motion, at a minimum, and active range of motion is tested whenever possible. Joint effusions may indicate intraarticular disease (i.e., ligamentous or intraarticular fracture). The joints are manually stressed to assess the integrity of the ligamentous structures. A neurovascular examination is performed and documented for each extremity. Pulses are recorded and compared with the opposite uninvolved extremity when possible. Doppler signals are obtained when palpable pulses are not present or are weak. Measuring the ankle-brachial index (ABI) is important when vascular injury is suspected or could be present (i.e., tibia plateau fracture dislocation). Motor function and sensation must be documented for the extremity dermatomes in all patients. A high suspicion for compartment syndrome should be maintained at all times, including patients with increased pain or abnormally tense compartments. This should raise suspicion for acute compartment syndrome and prompt further evaluation, with fasciotomies performed emergently if diagnosed. Realignment and immobilization of long bone fractures should be done expeditiously, as these maneuvers help prevent further damage to underlying soft tissues, facilitate clot formation, reduce patient discomfort, facilitate transportation, and may prevent embolization of intramedullary contents.

Diagnostic Imaging

As a general rule, when imaging a specific MSK injury (e.g., tibia shaft fracture), radiographs of the joints above (e.g., knee) and below (e.g., ankle) the level of injury should also be obtained. Similarly, when an injury to a joint is suspected (e.g., knee), the bones above (e.g., femur) and below (e.g., tibia) should be imaged in addition to the dedicated radiographs of the injured joint. Adhering to this protocol not only helps to obtain multiple views of the injured segment, which in turn provides more information about the injury, but will also decrease the odds of missed injuries in adjacent bones and joints.

Another important tenet of MSK imaging is obtaining high-quality orthogonal images of each bone of interest. In many cases, the extremity will have deformity secondary to the injury, but it is important that standard radiographs are obtained in order to best evaluate the anatomy. This will not only allow for effective detection of injuries but will also provide information on the overall deformity pattern, including the displacement, angulation, and length. As an example, a fracture may appear minimally or nondisplaced in one plane but in another view will be significantly displaced (Fig. 40.6). If at any point a reduction of a fracture or dislocated joint is performed, imaging should be obtained after the reduction to verify and document improvement in fracture alignment or joint congruency.

Some patients will have anatomic variants or congenital deformities. In those cases, if there is a question regarding the presence of an injury, imaging of the contralateral, uninjured side can be very useful in determining what is normal for that individual patient. When finer detail is necessary—such as in the assessment of

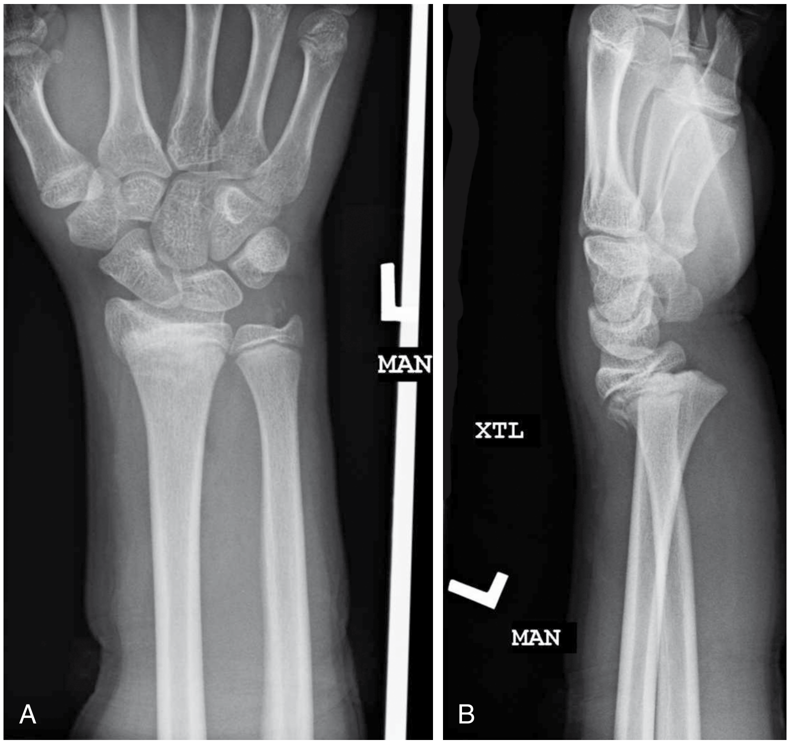

FIGURE 40.6 (A) Anteroposterior radiograph of the wrist showing disruption of the distal radial physis but adequate alignment. (B) Lateral view showing complete physeal separation with 50% dorsal displacement and significant angulation.

an intraarticular injury or to confirm the findings of an equivocal radiograph—a CT scan should be considered. Magnetic resonance imaging (MRI) has also become a particularly useful imaging modality as it has become easier to obtain for some institutions. It provides a more detailed evaluation of soft tissues (i.e., tendon or muscle injury), acute nondisplaced fractures, stress fractures (e.g.., femoral neck), spinal cord injuries, and intraarticular pathology (e.g., ligamentous injury). Its role in the trauma setting continues to expand, providing detailed information on spinal cord injuries and occult femoral neck fractures. It some situations in which plain radiographs are normal but high suspicion for an occult fracture remains, an MRI can be considered for further evaluation.

Shoulder

Multiple radiographic views of the shoulder can be obtained, and each helps to better evaluate specific anatomic structures of the shoulder girdle. In general, it is recommended to obtain a four-view series of the shoulder, which includes an AP, true AP ("Grashey view"), axillary lateral, and scapular "Y" view of the shoulder (Fig. 40.7). The most important lateral view is the axillary lateral because this will confirm a diagnosis of an anterior or posterior shoulder dislocation (Fig. 40.8). To obtain this image, the tube is angled cephalad, with the plate on the superior aspect of the abducted shoulder. This view is often difficult to obtain because of pain or instability of the shoulder in the setting of trauma. In those cases, a Velpeau view, which is a modified axillary view, can be obtained and provides orthogonally equivalent images. To obtain this image, the patient leans backward approximately 30 degrees over the cassette on the table. The x-ray tube is positioned cranial to the shoulder, and the beam is projected vertically down through the shoulder onto the cassette (Fig. 40.9). This allows the radiograph to be taken with the shoulder adducted and, in a sling, allows acquisition of the axillary images without the pain of shoulder abduction. Another useful radiographic view is the scapula "Y" view, and this is an image of the scapula down its long axis (Fig. 40.10).

Elbow

AP and lateral views of the elbow provide visualization of most of the bony anatomy. Internal and external oblique views are included in a complete elbow series and allow better visualization of the medial and lateral epicondyles. On the lateral view, it is important to look for the fat pad sign, or "sail sign," which can be indicative of a joint effusion from an occult fracture. The "sail sign" is produced when hemarthrosis from an intraarticular fracture displaces the anterior and posterior fat pads out of the coronoid and olecranon fossae, respectively. On radiography, the visualized fat pads resemble a sail (Fig. 40.11). Although the anterior fat pad can be visualized in a normal elbow, the presence of a posterior fat pad sign is strongly suggestive of an occult fracture and, if clinically appropriate, warrants a CT scan and consideration for an MRI in pediatric patients. In patients with a supracondylar distal humerus fracture, a CT scan is often ordered to assess for intraarticular extension and for preoperative planning. A traction view of the elbow may also be obtained in cases of comminuted distal humerus fractures to better understand the fracture pattern.

Forearm and Wrist

The forearm should be imaged entirely on a single x-ray cassette in both the AP and lateral planes. The elbow and wrist should always be included. The radius and ulna have a complex relationship, essentially acting as a joint as the radius rotates around the

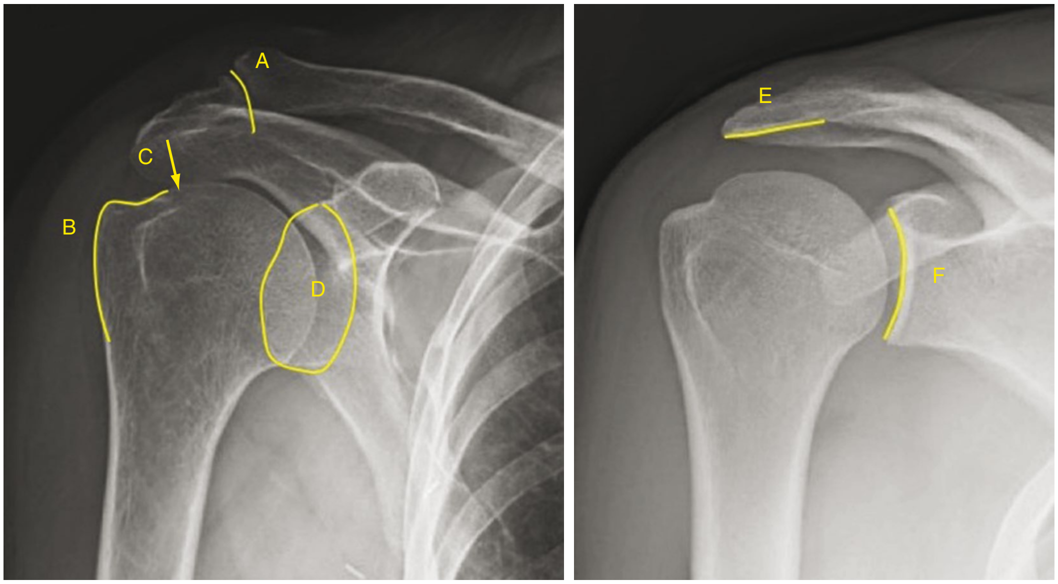

FIGURE 40.7 Anteroposterior view of the shoulder showing the acromioclavicular joint *(A)*, greater tuberosity *(B)*, acromiohumeral distance of 7 mm on average *(C)*, and glenoid fossa viewed at an angle to its face *(D)*. Grashey view of the shoulder showing the acromion down its longitudinal axis *(E)* and the glenoid fossa down its longitudinal axis *(F)*.

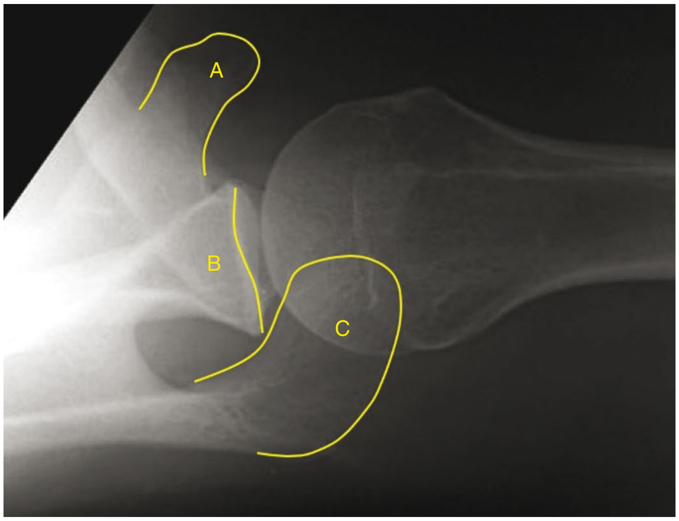

FIGURE 40.8 Axillary lateral view of the shoulder showing the coracoid process *(A)*, glenoid fossa *(B)*, and acromion process *(C)*. This view allows for the assessment of anterior-to-posterior translation of the humeral head relative to either the glenoid fossa (dislocations) or the humeral shaft (fractures).

ulna with forearm supination and pronation. Injuries may occur to each bone in isolation; however, both bones and their articulations at the elbow and wrist are often involved in some way. For example, an Essex-Lopresti injury describes a radial head fracture with an associated disruption of the forearm interosseous membrane and a dislocation of the distal radioulnar joint (DRUJ). A Monteggia fracture is another example in which the proximal ulna is fractured and a radial head dislocation also occurs as part of the injury. Finally, the wrist should be imaged in the AP, oblique, and lateral views. Do not forget that it is important that any distal radius or wrist injury that undergoes a closed reduction and splinting should have postreduction imaging as well.

Pelvis and Acetabulum

The pelvis is among the more complex three-dimensional bony structures of the human skeleton, and because of that, imaging can be difficult to evaluate by the untrained eye. CT scans ordered as part of the trauma protocol workup generally include a

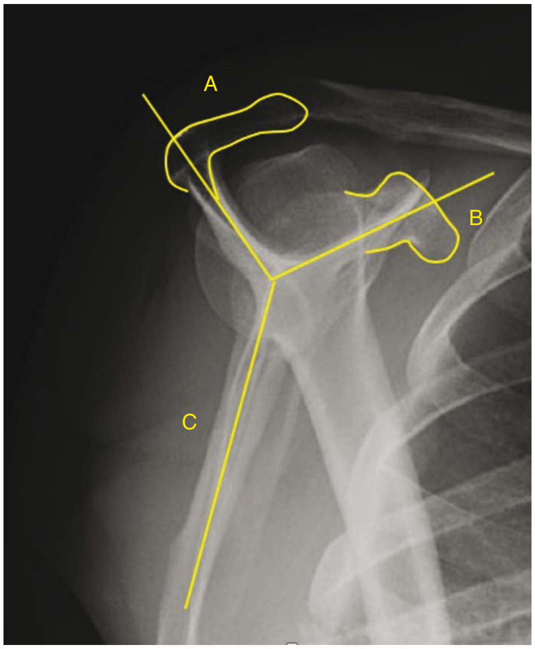

FIGURE 40.10 Scapula "Y" view showing the acromion process *(A),* coracoid process *(B),* and scapula body *(C).* This view allows for the assessment of anterior-to-posterior translation of the humeral head relative to either the glenoid fossa (dislocations) or the humeral shaft (fractures).

CT scan of the pelvis, and so some may argue against the necessity of plain radiographs. However, pelvis radiographs remain important to orthopedic surgeons because they allow for the visualization of the entire pelvis in one image. The standard AP radiograph of the pelvis provides an immense amount of information on the pelvic ring, acetabulum, hip joints, and proximal femurs. If pathology is confirmed on the initial AP radiograph or suspected on physical examination, additional views can be obtained. The first of these include the Judet views, or 45-degree oblique views, which are termed the *obturator oblique* and *iliac oblique views.* These are used to evaluate the acetabulum and give detailed information regarding specific components of the acetabulum (Fig. 40.12). It is recommended that all acetabular fractures are evaluated with an AP radiograph and both Judet views.

Inlet and outlet views of the pelvis are obtained to evaluate the pelvic ring, sacroiliac joints, and sacrum and to better characterize the deformity pattern of the pelvis. The inlet view is taken with the beam angled 25 to 40 degrees caudal to be perpendicular to the anterior cortex of the upper sacral body. Fractures of the sacrum, displacement of the sacroiliac joints, and displacement of the pubic symphysis in the AP plane are best evaluated on this view. The outlet view obtained with the beam angled 20 to 45 degrees cephalad, which views the sacrum, is pictured en face and gives information on the cranial-caudal translation of the injured pelvis.

Pelvic CT has become standard of care in many institutions for the evaluation of fractures of the pelvic ring, sacrum, and acetabulum. This provides much greater detail regarding fractures of the sacrum and acetabulum and greatly helps surgeons formulate a preoperative plan. It also allows for detailed measurement of fracture displacement, articular surface impaction, and the presence of any intraarticular fracture fragments. Finally, in patients with hemodynamic instability suspected to be caused by a pelvic or acetabular fracture, CT with IV contrast helps identify sources of hemorrhage and locations of hematomas. MRI has little role in acute, traumatic pelvic ring and acetabulum injuries; however, it is an imaging modality of choice for evaluating stress fractures, osteomyelitis, pelvic abscesses, and malignancies.

Hip

A hip series consists of AP and cross-table lateral radiographs. A plain AP pelvis radiograph should also be ordered to allow for comparison to the contralateral side. The cross-table lateral radiograph is generally recommended over the frog leg lateral in trauma patients because in the setting of a hip fracture, it will allow for less manipulation of the injured extremity. In an adult patient with acute groin pain and inability to bear weight with negative radiographs, it is critical to have a high suspicion for an occult femoral neck or intertrochanteric femur fracture, and this can be diagnosed with an MRI. Failure to identify these injuries can result in progression into a complete and displaced fracture, which can have a significantly negative impact on the patient's outcome. There is also a well-established association between a high-energy femoral shaft fracture (typically comminuted mid-to-distal shaft) and an ipsilateral femoral neck fracture. This was first described in 1953 and has since been reported to have an incidence between 2% and 9%.[7–9] Because of increased awareness, it is recommended that thin-cut high-resolution CT scan of the hip be ordered to assess for occult fracture. However, CT remains imperfect in the diagnosis, and, as such, new protocols have been developed for rapid limited-sequence MRI to diagnose occult femoral neck fractures missed on plain radiographs and thin-cut CT scans[8,9] with very positive results.

Knee

AP, lateral, and oblique (internal and/or external) radiographs will visualize most traumatic bony injuries of the knee. If possible, standing films are useful for evaluating knee alignment and joint space narrowing if there is concern for osteoarthritis; however,

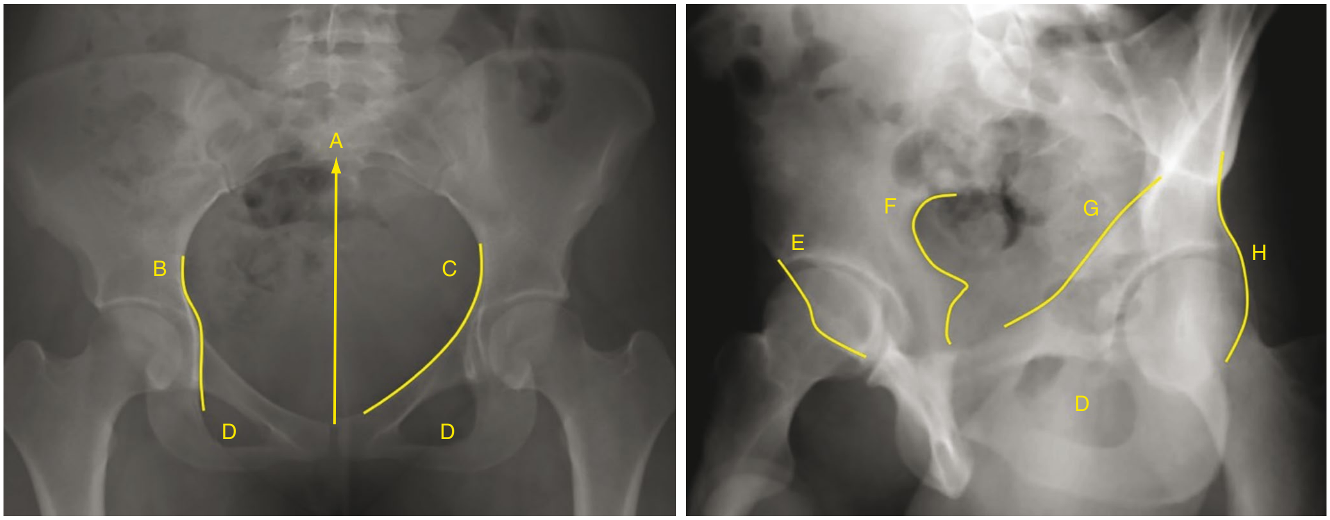

FIGURE 40.12 Anteroposterior and Judet pelvic radiographs. *(A)* The pubic symphysis should line up with the center of the sacrum to ensure no rotation. *(B)* The ilioischial line. *(C)* The iliopectineal line. *(D)* The obturator foramen are even in size and shape, ensuring no rotation. The obturator oblique is so named because the obturator foramen is visualized en face. The obturator oblique of one acetabulum is the iliac oblique of the contralateral hip in which the *(E)* anterior wall and *(F)* the posterior column are visualized. The *(G)* anterior column and *(H)* posterior wall are visualized on the obturator oblique.

most trauma patients will not be able to stand for imaging studies. Imaging both knees on a single weight-bearing AP allows for easy comparison to the contralateral side. The lateral radiograph can show an effusion, patellar fracture, posterior tibial plateau fracture, or tibial tubercle fracture. Assessment for patella baja (distal displacement) or alta (proximal displacement) can provide information if there is a suspected quadriceps tendon or patellar tendon rupture, respectively. If there is any doubt as to the degree of articular involvement, displacement, or depression, a CT scan should be ordered (Fig. 40.13). Although MRI can be helpful in the acute setting, evaluation for ligamentous, meniscal, or osteochondral injury can be performed in the outpatient setting. In the setting of a knee dislocation, there should be high suspicion for a vascular or neurologic injury. Serial measurements of the ABI in addition to assessment of distal pulses (palpation or Doppler) are important for diagnosing vascular injury. If there is any asymmetry in vascular examination, additional imaging such as CT angiography or MR angiography should be strongly considered.

Ankle

The majority of ankle injuries are rotational in nature, and similar to the forearm, the tibia and fibula are connected by ligaments and an interosseous membrane throughout the length of the leg. As a result of this relationship, ankle injuries may have an associated proximal fibula injury as part of the same injury mechanism. An example of this would be a Maisonneuve fracture, which is a spiral fracture of the proximal fibula with an associated syndesmotic injury and a deltoid ligament rupture or medial malleolus fracture. To ensure an injury like this is not missed, it is recommended to obtain formal tibia/fibula radiographs in addition to a formal ankle series.

Assessment of ankle mortise congruency is a key tenet in the evaluation of ankle injuries, and the stability of the mortise depends on both bony and ligamentous support. It is recommended that a standard three-view series of radiographs (AP, mortise, and lateral) be obtained when evaluating any ankle injury. Most ankle fractures can be diagnosed from these three views, and, although ligamentous structures are not visualized directly, assumptions about their integrity can be made by evaluating spaces with well-established values between the tibia and fibula. Three main parameters commonly used are the tibiofibular overlap, tibiofibular clear space, and medial clear space (Fig. 40.14). The tibiofibular overlap and clear space are generally measured on the AP radiograph, and the medial clear space is best measured on the mortise radiograph. When internally rotating the ankle from the AP to the mortise view, the medial clear space and tibiofibular overlap will change, but tibiofibular clear space should remain constant.

Although bimalleolar and trimalleolar ankle fractures are usually indicated for surgery, isolated distal fibula (i.e., lateral malleolus) fractures can potentially be treated nonoperatively with a splint or fracture boot. A radiographic stress examination should be performed when evaluating any isolated lateral malleolus fracture. The ankle is stressed on the mortise radiograph and can be performed manually (neutral dorsiflexion and external rotation of the ankle) or by using gravity, and these are generally considered equivalent. The latter is performed by lying the patient on the ipsilateral side with a stack of sheets under the lateral leg. This allows the affected ankle to hang freely to the lateral side. In a positive stress examination, either or both the medial clear space and the tibia-fibula clear space will widen, indicating an unstable ankle mortise, which should be evaluated for surgical intervention.

As noted in earlier sections, articular injuries of the tibial plafond (i.e., pilon fractures) generally require a CT scan for more detailed evaluation of the injury and preoperative planning. However, an important point to make in pilon fractures is that they commonly are initially treated in an ankle-spanning external fixator until soft tissues become amenable for definitive treatment. Therefore, orthopedic surgery specialists often recommended that a CT scan be obtained *after* application of the external fixator; the same is often true with tibial plateau fractures.

Foot (Hindfoot and Midfoot)

When foot trauma is suspected, the workup should start with a standard three-view series of AP, lateral, and oblique radiographs of the foot. The bony anatomy of the foot is a complex three-dimensional structure, and as a result, the standard series of films may not always be adequate to visualize certain bones. In the case of a calcaneus fracture, a Harris axial view should be added to evaluate the varus-valgus deformity of the tuberosity and to better visualize fractures in the sagittal plane. The Böhler angle of the calcaneus is measured on the lateral radiograph; it is the angle between a line from highest point of anterior process to highest point of posterior facet and a line tangential to superior edge of tuberosity (Fig. 40.15). The normal range for a Böhler angle is between 20 and 40 degrees, and values lower than this indicate depression of the posterior facet. The angle of Gissane may also be measured to evaluate the posterior facet, and a Broden view can be obtained to better visualize the posterior facet articular surface.

For fractures of the talus, the standard three-view foot series should be obtained. The lateral view will reveal fractures of the neck or body, and all views together should be assessed to confirm congruency of the tibiotalar, subtalar, and talonavicular joints. A Canale view is best for demonstrating talar neck fractures. If radiographs are negative or equivocal and the patient has evidence of fracture—ecchymosis, pain out of proportion to plain film findings, significant soft tissue swelling—a CT scan can be ordered to further evaluate. In general, most talus and calcaneus

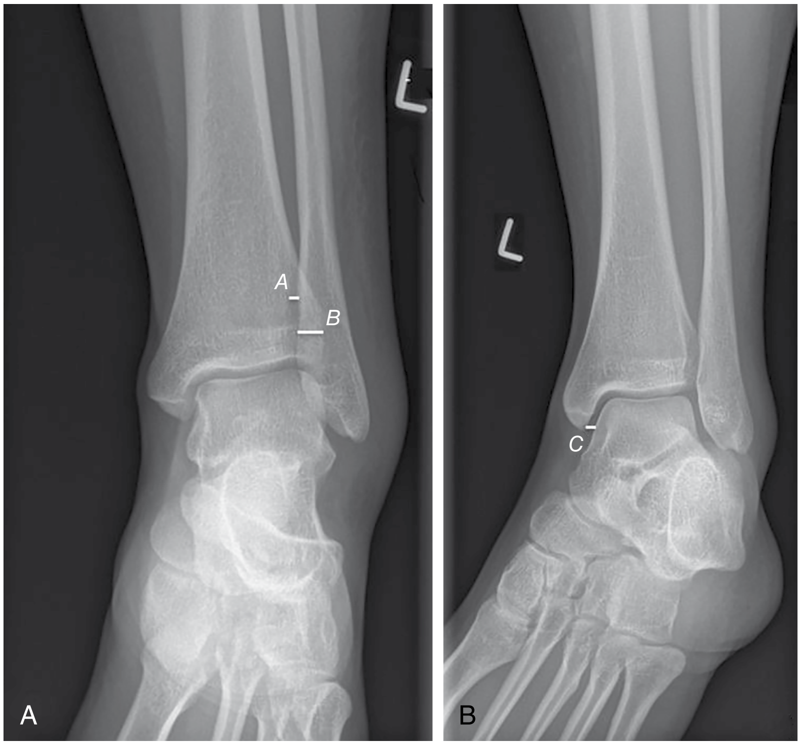

FIGURE 40.14 (A) Anteroposterior and (B) mortise radiographs of the ankle showing tibia-fibula clear space *(A)*, tibia-fibula overlap *(B)*, and medial clear space *(C)*.

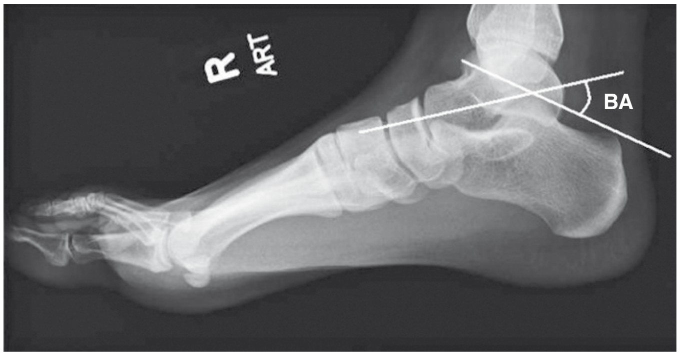

FIGURE 40.15 Lateral radiograph of the foot showing Bohler angle *(BA)*.

fractures should have a CT scan ordered to allow the orthopedic provider to better understand the fracture pattern and determine its surgical candidacy. Finally, with the exception of suspected osteomyelitis, deep abscess, or stress fracture, MRI of the foot is rarely indicated in the emergency setting.

Wound Management

All wound dressings and splints placed in the field or at an outside hospital should be removed to evaluate the wounds for their severity and degree of contamination and to determine whether there are any open fractures. If an open fracture is suspected, tetanus prophylaxis and appropriate antibiotic prophylaxis should be given immediately to reduce the risk of infection.[5,6] Using sterile technique, wounds should then be irrigated with sterile saline to remove superficial gross contamination such as dirt, gravel, or grass in the emergency department. Soft tissue bleeding can be controlled by direct manual pressure, followed by application of sterile dry dressings. After sterile dressings are placed over the wounds in the emergency department, they should remain in place until the orthopedic specialist evaluation, ideally at the time of operative irrigation and debridement. Immobilization of the fractured extremity is then carried out in the same manner as for a closed injury to allow for soft tissue rest and hemorrhage control.

Reduction and Immobilization

All displaced fractures, fracture-dislocations, and joint dislocations should be gently and promptly reduced to restore general limb alignment. The injured extremity is then properly splinted to maintain the fracture reduction, and postreduction radiographs should be obtained to confirm acceptable reduction. Reductions generally require analgesia in the form of a hematoma block with local anesthetic, intravenous narcotics, or conscious sedation to allow for appropriate relaxation of the patient. Hip and shoulder dislocations are a good example in which muscle spasm can prevent successful reduction, and in those instances, it is important to ensure adequate sedation is achieved. If a joint reduction is unsuccessful after adequate sedation and relaxation, general anesthesia may be necessary. However, it is critical to ensure that the patient does not have an irreducible hip fracture-dislocation, as more aggressive attempts at reduction may result in iatrogenic femoral neck fracture (Fig. 40.16).

Reduction maneuvers follow the same general set of principles for all fracture and dislocation types. First, in-line traction is applied to the limb after sedation is administered and allowed time to become effective, often requiring a provider trained in moderate sedation. If the soft tissue envelope surrounding the fracture is intact, in-line traction alone may produce satisfactory alignment through ligamentotaxis. In most cases, the deformity must be recreated and exaggerated to allow for appropriate mobilization and reduction. It is important that neurovascular status is documented before and after any reduction maneuver or splint application. Once satisfactory reduction or alignment is achieved, it must be maintained by immobilization through casting, splinting, or traction. Immobilization of the joints above and below the fracture is generally recommended to ensure adequate stability and prevention of a lost reduction. Postreduction radiographs are required to confirm reduction. Nondisplaced fractures are splinted in a similar manner, but without a formal reduction maneuver. Most nondisplaced fractures do not require surgical treatment, and therefore, high-quality splints should be applied, as they may remain in place for 2 to 3 weeks. Splints are placed initially and then often exchanged to circumferential casts in the outpatient setting after the swelling subsides.

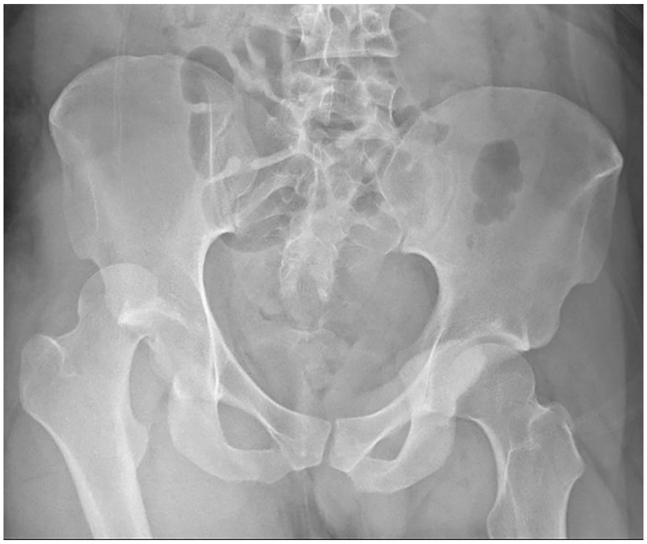

FIGURE 40.16 Anterior-posterior radiograph of irreducible hip fracture dislocation.

It is recommended that ligamentous injuries are immobilized with either a splint or brace depending on the injury. The joint is fully evaluated as described earlier, and a thorough neurovascular examination is performed on the limb. Frequently, joint effusions, hemarthroses, or lipohemarthroses are present, which indicate the presence of an intraarticular injury. Therapeutic aspiration of a traumatic hemarthrosis is not recommended because of the risk of iatrogenic infection in the unsterile environment of the emergency department. After a successful reduction, the joint should then be immobilized and can be reevaluated after the acute pain and swelling decrease.

The rationale for immobilization is threefold. First, a well-padded splint applies stabilization and compression to the soft tissues, which will aid in decreasing further bleeding and soft tissue swelling. Second, providing appropriate immobilization and stability to the injured extremity may prevent further soft tissue injury to an otherwise already traumatized soft tissue envelope. Third, immobilization of the fracture reduces the patient's discomfort and facilitates transportation and radiographic evaluation of the fracture(s). There are a variety of different splinting techniques, and they vary depending on which body part is being immobilized. For example, a volar splint, ulnar gutter splint, or thumb spica split is often used for fractures of the hand. A sugar tong splint (Fig. 40.17A–D) is indicated for wrist or forearm

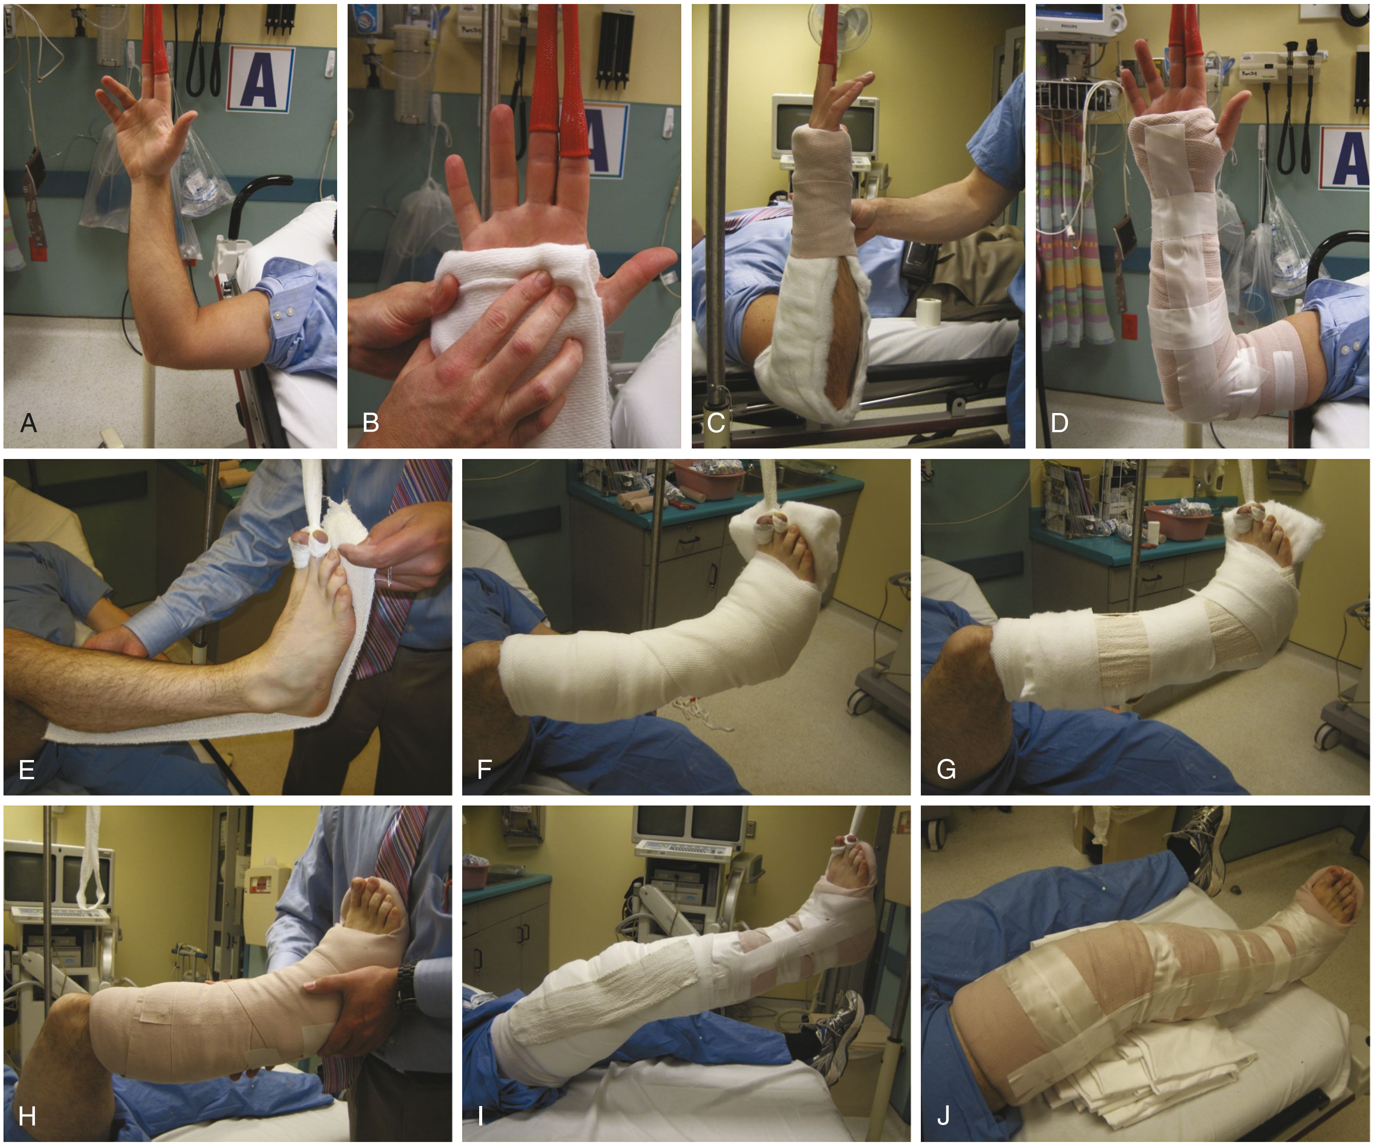

FIGURE 40.17 Application of sugar tong (A–D), short leg (E–H), and long leg (I–J) splints. (A) Finger traps are used to apply gravity traction. (B–C) A well-padded splint (plaster or fiberglass) is measured and applied to the limb. The splint should extend from the distal palmar crease volarly (B) to the metacarpophalangeal joints dorsally. This allows motion of the metacarpophalangeal joints. (D) The compressive wrap (bias bandage or elastic wrap) is applied and secured with tape. (E) Gravity traction is applied by hanging the limb by the toes in a figure-4 position across the bed. This serves two functions. First, flexion at the knee relaxes the pull of the gastrocnemius muscle across the ankle; second, the inversion produced by this position helps maintain fibular length and the reduction of the medial malleolus. Both a posterior slab and a U or stirrup component (plaster or fiberglass) are measured. (F) The limb is protected with a soft dressing (circumferential Robert Jones cotton). (G) The posterior followed by the stirrup splints are applied to the injured extremity and held in place with cast padding. (H) The compressive wrap (bias bandage or elastic wrap) is applied and secured with tape. When possible, the knee is flexed and the ankle is placed in neutral position to prevent equinus contracture. (I) The short leg splint may be extended into a long leg splint by protecting the remainder of the limb with a soft dressing and then applying medial and lateral side slabs overlapping the short leg splint and extending to the proximal thigh. (J) Again, the compressive wrap (bias bandage or elastic wrap) is applied and secured with tape.

fractures. This splint provides immobilization of the wrist and elbow, which effectively will also prevent pronation and supination of the forearm. Fractures about the elbow are placed in a posterior long arm splint. For humeral shaft fractures, a coaptation splint is used. If there is minimal swelling present with a humeral shaft fracture, a functional brace (i.e., Sarmiento brace) may be applied acutely in the emergency department. A short leg splint consisting of a posterior slab and a U or stirrup component (see Fig. 40.17E–H) is used for fractures of the foot and ankle. With the addition of side slabs crossing the knee, this splint can be extended into a long leg splint for tibial shaft plateau fractures or knee dislocations (see Fig. 40.17I–J). Once the cotton wrap and plaster have been applied, the splint can be gently wrapped with an ACE wrap or other nonconstrictive dressing.

An important concept to keep in mind when performing reductions and splinting is to appropriately mold the initial splint or cast in a way that will maintain the reduction. The natural tendency of many fractures is to displace back into their initial deformity. Molding of the splint is an important technique that should be implemented into every splint to maintain the reduction in the proper position. Common examples of this include a valgus mold for humeral shaft fractures to avoid displacement into varus deformity and a volar-directed mold for dorsally displaced distal radius fractures (Fig. 40.18).

Application of a circumferential cast is rarely indicated in the acute treatment of adult fractures, especially because soft tissues in the injured extremity will continue swell for 48 to 72 hours after injury. Thus, a circumferential cast that does not allow room for swelling can be too constrictive and could potentially lead to pressure necrosis or compartment syndrome. However, there are a few cases in which a cast will be the definitive treatment for a patient (i.e., most pediatric fractures and some nondisplaced fractures in adults). In these cases, it is recommended to "bivalve" the initial circumferential cast after it is applied, and this is done by cutting the fiberglass or plaster portion of the cast longitudinally on opposite sides to allow room for swelling. This technique remains effective in maintaining the reduction, more than an open splint, and after the soft tissues have been allowed time to rest (2–3 weeks), the cast is then overwrapped with fiberglass or plaster material at the first clinic visit.

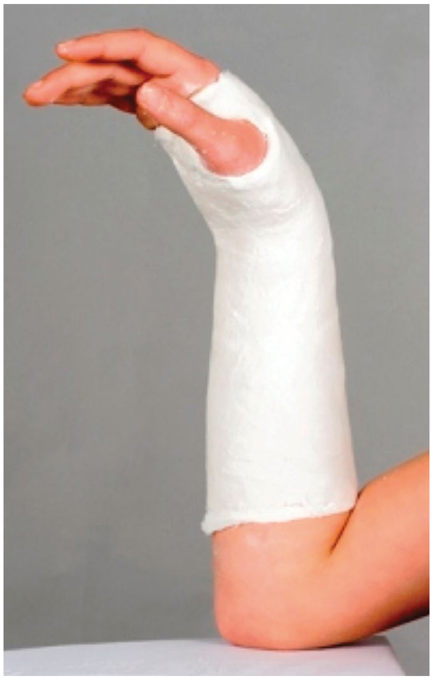

FIGURE 40.18 Distal radius mold. (From The Royal Children's Hospital, Melbourne, Australia. http://www.rch.org.au/fracture-education/management_principles/Management_Principles/.)

Traction

Immobilization of fractures in the pelvis, acetabulum, and proximal part of the femur can be difficult with traditional splinting techniques. A variety of forms of traction can be used in such situations to aid in fracture stabilization and pain control, and those include skeletal traction, skin traction, or traction splints. Skeletal traction has proved to be an effective alternative means of immobilization and may be placed through the distal femur or proximal tibia (Fig. 40.19). Common indications for its application include unstable pelvic ring and acetabular fractures, femoral shaft fractures, and injuries with intraarticular fracture fragments to offload the cartilage and prevent further joint injury from pressure necrosis. Skeletal traction is generally more effective and a safer option for patients in which the traction is intended to remain in place for a longer period of time (i.e., polytrauma patients

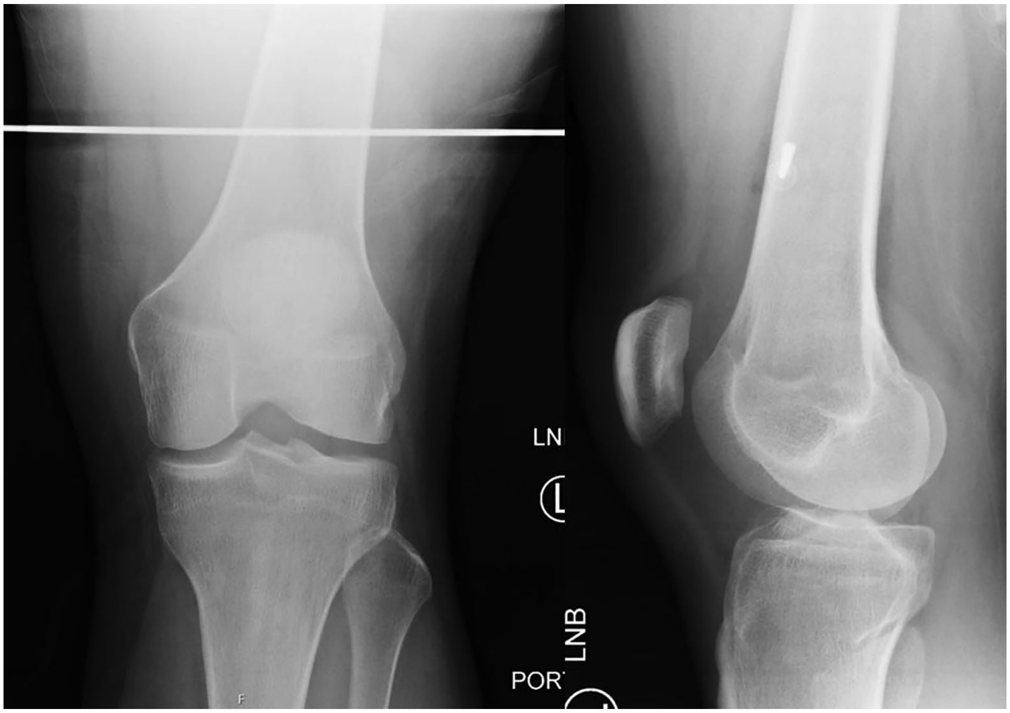

FIGURE 40.19 Distal femur skeletal traction pin.

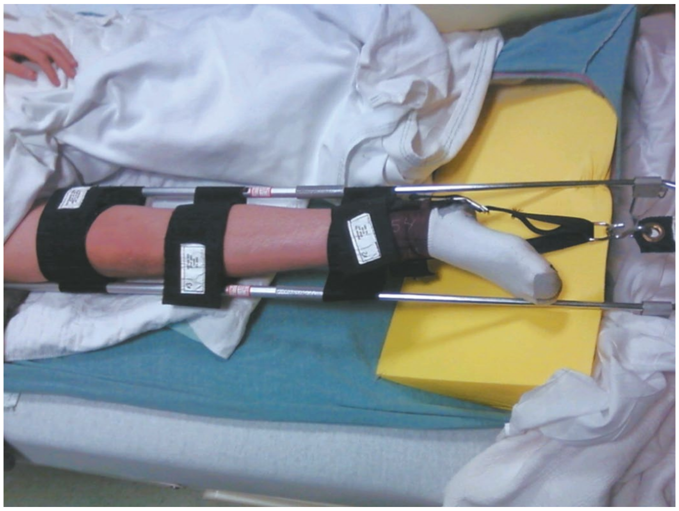

FIGURE 40.20 Hare traction splint placed at the scene of the accident to stabilize a femoral shaft fracture.

who may not be cleared for surgery). There are previously well-described techniques for placement of skeletal traction, with either a Kirschner wire or Steinmann pin, in anatomic "safe zones" to decrease the risk of complications and iatrogenic injury to local neurovascular structures. The most common complication of skeletal traction is superficial pin-site infection; however, the rate is very low (~0.6%) given that most pins are placed only for a short period of time. A recent review of placement of lower extremity skeletal traction in orthopedic trauma patients provides a detailed outline of indications, techniques for placement, and rate of complications.[10]

Skin traction (also known as *cutaneous traction* or *Buck's traction*) is similar to skeletal traction in that it imparts axial load on the limb to aid in length restoration, but it also differs in that it is noninvasive.[10] The primary complication of skin traction is local skin damage, sloughing, or necrosis, and, although this is rarely encountered, the risk must be evaluated before its use, especially in elderly patients with fragile skin. Traction splints, such as the Hare or Sager traction splint, may also be used. They use a ratchet-based form of traction that is distally docked to a frame that proximally rests against the patient's ischium and can be effective for femoral shaft fractures (Fig. 40.20). These are generally applied in the prehospital setting by emergency medical services personnel, but it is generally recommended that they be removed upon arrival to the emergency department to prevent skin complications. Overall, each method of traction has been shown to be effective in the setting of short-term use and carries its own set of advantages, disadvantages, and complications. When choosing one form over another for your patient, it is recommended to consider patient-related factors, timing of planned surgical intervention, and provider experience.

TIME-DEPENDENT ORTHOPEDIC INJURIES

Open Fractures

Open fractures can occur in young and elderly patients and after both high- and low-energy injury mechanisms, depending on the location of the body and the soft tissue envelope in that region. The majority of open fractures result from high-energy impact to the lower extremity (e.g., MVC), which results in significant soft tissue trauma, periosteal stripping, fracture comminution, and contamination. Management of these injuries often requires a multidisciplinary approach involving orthopedic surgeons, plastic surgeons, and vascular surgeons. By definition, an open fracture communicates with the outside environment through a soft tissue wound that may be located either directly over the fracture site or several centimeters away. The mechanism may be considered "inside-out," which means that as the fracture occurred, the bone lacerated out through the soft tissues into the outside environment (e.g., tibia shaft fracture), or "outside-in," which means the bone was fractured from something that penetrated through the soft tissues (e.g., knife stabbing). Regardless of the mechanism, most open fractures require a prompt history and physical examination, stabilization, systemic antibiotics, debridement and irrigation, temporary or definitive fixation, and, if needed, soft tissue coverage and/or vascular repair.

Classification

Several classification systems have been developed and used to guide appropriate management and outcomes of open fractures. The most commonly used and recognized classification scheme is the Gustilo-Anderson classification system, which evaluates open fractures on the basis of the size of the wound, the degree of contamination, and the extent of the soft tissue injury (Table 40.4).

The primary prognostic value of this classification system is the increasing risk of infection with each successive open fracture

TABLE 40.4 Gustilo-Anderson Classification of Open Fractures

FRACTURE TYPE	DESCRIPTION	RECOMMENDED PROPHYLACTIC ANTIBIOTICS
I	Wound <1 cm, clean; most likely inside-to-outside lesion; minimal muscle contusion; simple transverse or oblique fracture	First-generation cephalosporin
II	Wound >1 cm with extensive soft tissue damage, flaps, or avulsion; minimal to moderate crushing; simple transverse or short oblique fracture with minimal comminution	First-generation cephalosporin ± aminoglycoside
III	Extensive soft tissue damage including muscle, skin, and neurovascular structures; often a high-velocity injury with a severe crushing component (barnyard injuries)	First-generation cephalosporin + aminoglycoside + penicillin G
IIIA	Extensive laceration, adequate soft tissue coverage; segmental fracture; gunshot injuries	
IIIB	Extensive soft tissue damage with periosteal stripping and bone exposure necessitating formal soft tissue coverage; usually associated with contamination	
IIIC	Any open fracture with vascular injury requiring repair	

From Gustilo R, Mendoza R, Williams DN. Problems in the management of type III (severe) open fractures. *J Trauma*. 1984;24:742-746.

type. Multiple previous studies have reported infection rates of 0% to 2% for type I, 2% to 10% for type II, and 10% to 50% for type III fractures, with type IIIC fractures exhibiting the highest rates of infection.[11–13] Overall, this classification system is a practical guide to management, but it does have limitations, such as poor interobserver reliability that has been shown to range from 42% to 94%.[14,15] This is thought to be because the system inaccurately assesses the true extent of deep soft tissue injury (i.e., soft tissue stripping), which is why true scoring can only be made at the time of surgery.

For example, in Fig. 40.21A, a clinical photo of the lateral aspect of an ankle is shown with two small, minimally contaminated soft tissue wounds. The radiograph of the underlying fracture is displayed in Fig. 40.21B. Strictly from the clinical appearance of the soft tissue injury, this would likely be classified as a type I open distal tibia and fibula fracture in most cases. However, taking the underlying fracture pattern into consideration would more appropriately classify this injury as a type IIIA open fracture. This is because the injury mechanism was a high-energy MVC, with fracture site comminution, mottling and contusion of the soft tissues, and air densities throughout the soft tissues on the radiograph suggesting a more extensive soft tissue injury. Thus, it is critical to consider all pieces of information available to you when assigning the diagnosis because it will affect your decision on acute treatment (e.g., prophylactic antibiotics) and possibly the patient's outcome. As discussed earlier, it can be helpful to categorize injuries into either *high*- or *low*-energy injuries based on the mechanism, fracture pattern, and degree of soft tissue injury. In doing so, low-energy injuries will be more appropriately classified as types I and II, and high-energy injuries will be types IIIA–C.

Initial Management

The initial management is the same as all other high-energy traumatic injuries: a thorough understanding of the injury mechanism and appropriate treatment for other injuries based on the ATLS protocol. Table 40.5 is an example of our institution's open fracture protocol, and another can be found in a recent review on antibiotic prophylaxis in open fractures.[6] Although the details may differ between institutions, it is important that each institution have an algorithm similar to this to help guide treatment.

The most important aspect of the treatment of open fractures is the early administration of antibiotics.[5,6,12] It is strongly recommended that antibiotics be administered within 1 hour of injury to the emergency department and, if possible, as soon as they arrive. Additionally, previous studies have suggested that the 1-hour time limit should begin at the time of injury, and thus, some institutions have implemented protocols for prehospital antibiotic administration for severe open fractures.[16]

The concern for infection is what motivates the use of prophylactic antibiotics, and as many previous studies have shown significant decreases in rates of infection after their administration, traumatic open injuries continue to remain responsible for up to 19% of cases of osteomyelitis.[17] The antibiotic regimen administered to each patient is generally dictated by the classification type; however, there is evidence for both seasonal and geographic variation in the organisms responsible for the infection.[18] As a result, there may be slight variation in protocols based on which organisms are more endemic to the particular region in which the institution is located. Discussion with infectious diseases specialists at your institution is recommended to ensure your chosen antibiotic protocol is providing adequate coverage.

It is recommended to provide coverage for gram-positive bacteria, such as *Staphylococcus* or *Streptococcus,* with systemic antibiotics at the time of presentation for type I and II fractures because they are the most commonly found bacteria in these injuries.[5] First-generation cephalosporins (e.g., cefazolin) have been the most common and effective agents given after open fractures, and early administration has been supported by multiple reviews.[5,6,11] In patients with a true penicillin allergy, alternative agents for coverage such as clindamycin have been recommended by the Surgical Infection Society. Additionally, in patients with a penicillin allergy presenting to hospitals with a high rate of community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin usage has been recommended. In patients with type III

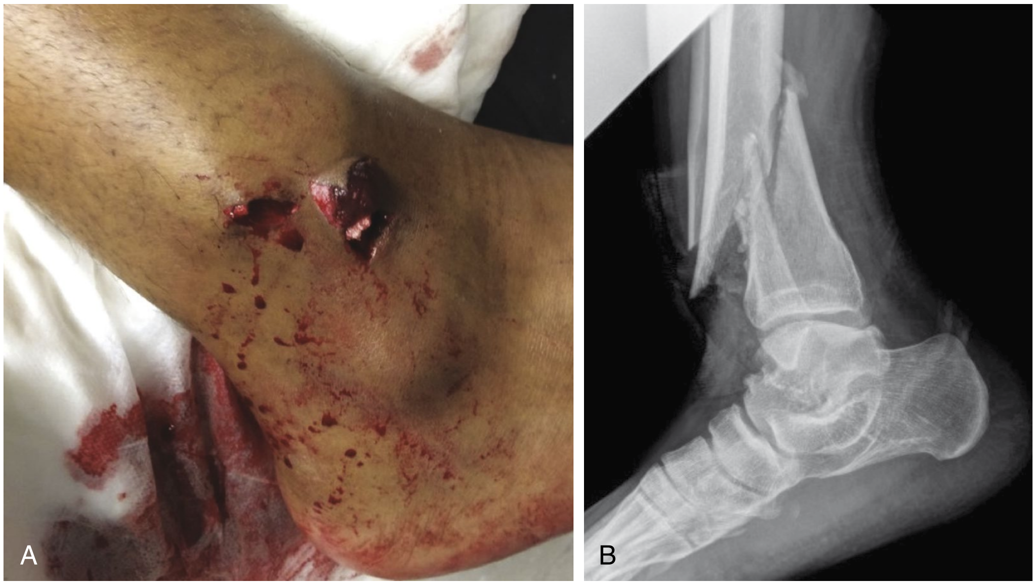

FIGURE 40.21 Two small lateral ankle lacerations (A) above a comminuted distal tibia fracture with intraarticular extension (B).

TABLE 40.5 General Guidelines for Open Fractures

Treatment Goals

- Systemic prophylactic antibiotic therapy initiated within 1 hour of arrival
- Operative debridement within 6–24 hours
- When necessary, soft tissue coverage within 7 days of injury

Prophylactic Antibiotics

Types I and II	Ancef	48 hours from presentation 24 hours after subsequent intervention
Type IIIA–C	Ancef/tobramycin	48 hours from presentation 24 hours after subsequent intervention
Soil contamination	Penicillin	Single dose
Marine contamination	Levaquin	Single dose
Ballistic fracture	Ancef/tobramycin	48 hours from presentation 24 hours after subsequent intervention
Transcolonic gunshot injury to the spine or pelvis	Vancomycin/cefepime/Flagyl	7 days from presentation 24 hours after subsequent intervention
Lawnmower injury	Unasyn	24 hours from presentation
	Augmentin	7 days postdebridement or presentation

Emergency Room Management

- Systemic prophylactic antibiotics (see earlier)
- Radiographs, bedside irrigation and removal of gross contamination from wound, fracture reduction, loose approximation of skin, dry sterile dressings, splint
- NPO, obtain acute care surgery clearance

NPO, Nothing by mouth.

open fractures, increasing severity of soft tissue injury, and soil-contaminated wounds, gram-negative coverage should be added to the antibiotic regimen, such as an aminoglycoside (e.g., gentamicin). In one series of 126 type III open fractures, the authors reported a significantly higher rate of acute kidney injury in patients treated with aminoglycosides.[19] In contrast, in a separate study of 167 patients with open fractures, the authors did not observe an association between aminoglycosides and acute kidney injury except in patients with higher injury severity scores and hypotension on presentation.[20] Nonetheless, its use has fallen out of favor in some institutions because of these reports of dose-dependent reversible nephrotoxicity and irreversible ototoxicity. Given those concerns and a lack of evidence supporting its clinical efficacy, the authors of a recent review article recommended against the use of aminoglycosides in routine prophylactic management.[6] Finally, providers should consider broader coverage in patients presenting with aquatic wounds contaminated by salt water (*Vibrio* species) and fresh water (*Aeromonas* and *Pseudomonas* species).[5,6]

Delayed administration has been shown to increase the risk of infection markedly, especially if given longer than 66 minutes after injury.[21,22] In addition to timing of administration, the duration of prophylactic antibiotic therapy should also be taken into consideration.[23,24] Prolonged antibiotic therapy past 24 hours has not demonstrated a notable decrease in infection risk, including in type III open fractures. Studies comparing infection rates in patients treated for 24 hours or 5 days of antibiotic treatment have shown no difference in infection rates, and several review articles have demonstrated similar results at cutoffs of both 24 and 72 hours.[6,23,24] A recent systematic review recommended discontinuation of prophylactic antibiotics after 24 hours of therapy in type I and II open fractures and after 72 hours or 24 hours after wound closure/coverage (whichever occurs first) in type III open fractures.[23]

The appropriate timing of surgical debridement remains a controversial topic, with much of the available evidence conflicting, yet it is generally accepted that timely surgical management is of paramount importance. Classically, the recommendation was for initial debridement to be performed within the first 6 hours after injury. However, multiples studies have since demonstrated that the historical "6-hour rule" for debridement offers little benefit over debridement performed within 24 hours of injury for type I and II open fractures.[25,26] Regarding more severe type III open fractures, a recent meta-analysis showed an increased infection risk when surgical management was delayed more than 12 hours, which led to the recommendation of operative debridement within 12 hours of injury for type III injuries.[26] Similar results were reported in a retrospective analysis of 10,651 open tibia and femur fractures in the Surgical Implant Generation Network (SIGN) surgical database, with the probability of infection increasing by 0.23% for every 6-hour delay in debridement in type III injuries and 0.13% in type I and II injuries.[27]

Local antibiotic therapy, such as intrawound powdered antibiotics or antibiotic cement spacers/beads, has experienced increasing popularity for the treatment of both open and closed fracture management and in other fields of orthopedic surgery. Soft tissue injury and vascular compromise can limit the delivery of intravenously administered antibiotics to fracture sites. Thus, the benefits of locally delivered antibiotic agents have the ability to obtain a higher concentration at the surgical site, while also limiting the potential for systemic toxic levels of the drug.[28–30] Some authors have expressed concern that administration of local antibiotics may increase the risk of developing drug-resistant organisms; however, there is a paucity of literature to support this. A recent study evaluated the species distribution and resistance patterns of organisms causing surgical site infection with and without the use of local antibiotic powder and reported no measurable increase in infections caused by antibiotic-resistant organisms.[31] Two recent reviews demonstrated similar results, reporting a potential 23% reduction in the odds of deep surgical site infection[32] and significantly decreased the overall incidence of infection in both open and closed fractures.[33]

When performing surgical debridement, it should be done in a systematic manner and one that includes meticulous handling of the soft tissues. Debridement should begin in the superficial layers and progress to deeper layers. All foreign and devitalized tissue should be removed, including any bone without soft tissue attachments. In higher-energy injuries, the zone of injury may take several days to demarcate itself, and, because of that, the wound should undergo serial debridement every 48 to 72 hours until a stable and healthy soft tissue bed is obtained. Determination of soft tissue and muscle viability during debridement is a subjective process. Evaluation of muscle viability by the "4 Cs" of color, contractility, consistency, and capacity to bleed were established tenets of debridement decades ago and have served as a general guideline for many when performing debridement. However, a recent histopathologic study found that neither the "4 Cs" nor the surgeon's impression correlate with muscle viability and suggested the possibility that surgeons may be debriding potentially viable muscle.[34]

The method of irrigation and the solution used during the irrigation have also been studied. The FLOW study sought to investigate the effects of castile soap versus normal saline solution delivered by three different irrigation pressures in 2447 patients with open fractures.[35] They reported no difference in rates of reoperation based on irrigation pressure; however, the reoperation rate was higher in the soap group than in the saline group. Earlier studies in animal models demonstrated higher rates of bacterial seeding of the intramedullary canal and myonecrosis of the soft tissues with high-pressure irrigation methods in animal models; however, this was confirmed to be clinically relevant in the FLOW study. Additional studies have investigated the effect of different irrigation solutions such as bacitracin versus castile soap solution, saline versus iodophor and hydrogen peroxide, saline versus chlorhexidine, and saline versus distilled water. Overall, no advantages were seen in using nonsaline solutions, and in some studies, more wound healing disturbances and adverse wound inflammation were seen with use of antibiotic additive and antiseptic solutions. Finally, with regard to volume of irrigation solution used, there are no reliable data to provide formal recommendations.

In situations where the wound cannot be closed primarily or there is concern for progression of soft tissue necrosis, negative-pressure wound therapy (NPWT; i.e., vacuum-assisted closure) is recommended. In theory, the device removes blood and draining fluid from the wound and may potentially increase the formation of granulation tissue. The results of a prospective randomized trial known as the "UK Wound management of open lower limb fractures (UK WOLLF)" study did not show any difference in surgical site infections or quality of life between patients treated with NPWT versus standard sterile dressings.[36] Similarly, in a recent Cochrane review, the authors concluded that it remains uncertain whether NPWT is superior to standard sterile dressings in wound infection, adverse events, or time to closure/coverage.[37] In contrast, in the 2023 American Academy of Orthopaedic Surgeons (AAOS) clinical practice guidelines for prevention of surgical site infection after major extremity trauma, the role of NPWT was considered and received a strong recommendation in both open and closed fracture situations.

The discussion of fixation and soft tissue reconstruction strategies for open fractures is well beyond the scope of this text because the timing of both temporary and definitive fixation of open fractures is at the treating surgeon's discretion with regard to the status of the soft tissue envelope cleanliness of the fracture site. In general, after the secondary survey is completed and necessary diagnostic studies are obtained, a multiply injured patient may be quickly transferred to the operating room for intervention. In polytraumatized patients, the trauma surgeon generally serves as the primary coordinator of care, consulting with the anesthesiologist, neurosurgeon, and orthopedic surgeon to determine the most appropriate treatment algorithm for each patient. Critical procedures to address life-threatening injuries are prioritized, and timing of subsequent interventions is continuously reviewed as the patient's status evolves.

Limb Salvage Versus Primary Amputation

Although beyond the scope of this chapter, the absolute indications for primary amputation are few, and as such, the decision-making algorithm must involve evaluation and recommendation from a multidisciplinary team (if possible), with formal documentation of recommendations and detailed accounts of injury severity uploaded to the patient's medical record. In some instances, life must be chosen over limb, but, if at all possible and if the situation allows, temporary operations can be performed initially until a formal discussion can be held with the patient and their family regarding goals of treatment. The decision between primary amputation and salvage of a severely injured extremity is complex and should involve input from multiple providers in multiple disciplines (i.e., orthopedic, trauma, and vascular surgery). It can be beneficial for consulting services such as physical medicine and rehabilitation physicians or prosthetics team members to provide additional information to help reach a decision. A key tenet of limb salvage is reconstruction of a functional extremity, including motor and sensory function to some degree, in order to give the patient the best chance for a good outcome. If amputation is chosen, multidisciplinary management with prosthetic and rehabilitation teams is critical, and patients should be screened for symptoms of depression and PTSD to ensure the patient's psychological health is cared for.

Fractures Secondary to Firearm Injury

In the United States, the incidence of firearm-related injuries and fractures has continued to increase despite an overall fall in the rates worldwide.[38] There have been more than 1 million nonfatal injuries resulting in emergency department visits in the United States since 2010, and in 2020, firearm-related injuries became the third leading cause of nonfatal violence-related emergency department visits.[38] These injuries are associated with substantial healthcare costs (estimated at \$2.5 billion in the first year) and significant socioeconomic consequences for both the patient and society. Historically, firearm injuries have been characterized by the type of firearm and the muzzle velocity of the firearm, which is divided into low velocity (<2000 feet per second [fps]) and high velocity (>2000 fps). The muzzle velocity directly correlates with the kinetic energy of the bullet, and therefore, the greater the kinetic energy of the bullet, the greater the energy that is imparted on the tissues upon impact.

In the United States, the majority of firearm-related fractures are caused by low-velocity weapons, and unfortunately, there is a paucity of high-level evidence in the literature regarding their management. In general, most low-velocity firearm-related fractures can be managed similarly to non–firearm-related fractures, with the goals of restoring function and decreasing the rate of complications. There are very few high-level studies to support the administration of prophylactic antibiotics in patients with nonoperatively treated injuries; however, a recent review found the majority of studies recommend a short course of prophylactic antibiotics to reduce the risk of infection, and no data suggest superiority of intravenous or oral administration.[38] Low-velocity wounds generally have minimal soft tissue injury, and routine operative debridement is not recommended unless grossly contaminated. Fixation of long bone fractures, in terms of indications and techniques, is similar to those of standard care for other fracture patterns (closed and open) and should be treated at the discretion of the attending surgeon.

Fractures caused by high-velocity firearms (muzzle velocity >2000 fps) are generally associated with a more severe and larger zone of injury to the soft tissues. The infection risk tends to be higher because of the increased amount of devitalized tissue, and because of this, it has been suggested that these injuries be treated similarly to type III open fractures.[38] Wounds often require repeat operative debridement, and in some cases, soft tissue reconstruction for coverage after the complete zone of injury has been identified. Furthermore, high-velocity firearms often produce larger areas of soft tissue cavitation with significant comminution and bone loss at the fracture site, higher rates of neurologic and vascular injuries, and, as a result, increased risk of nonunion and amputation.[38] Initial management should include administration of broad-spectrum antibiotics and tetanus prophylaxis to decrease risk of infection. Finally, depending on the overall extent of the soft tissue and bony injuries, it is at the surgeon's discretion whether to perform temporary or definitive fixation at the time of the initial debridement.

Firearm injuries with intraarticular involvement require special consideration because of a number of factors, which include periarticular fracture management, potential risk of septic arthritis, chondral damage from retained metallic fragments, and, historically, the concern for lead arthropathy. Suggested treatment algorithms have been well described in previous reviews and meta-analyses.[38] Antibiotic prophylaxis is a consideration in these injuries, and two previous meta-analyses recommended their use after reporting no significant difference in infection rates between patients treated with surgical debridement versus antibiotics alone.[38] In the case of retained intraarticular bullets or loose bodies, most studies recommend surgical removal and debridement of the joint, either through an open approach or arthroscopically. In doing so, it is thought to decrease risk of lead toxicity, septic arthritis, and further mechanical damage to the articular surface. Finally, the literature has not found a significant difference in infection rates in patients who did and did not undergo an operative debridement. However, the entire clinical picture should be taken into consideration, including the bullet characteristics, injury pattern, appearance of the wound and level of contamination, or presence of bowel contamination.

Firearm-related fractures of the hip, pelvis, and spine have high rates of associated perforated viscus and bowel injuries. Most authors have recommended surgical debridement of intraarticular fractures associated with an injury to the bowel. Several studies have assessed the rate of infection after nonoperative treatment and intravenous antibiotics alone, reporting rates ranging from 0% to 21%.[38] When an associated bowel or urinary tract injury is confirmed, it is recommended that gram-negative coverage be added to the antibiotic regimen. In the context of firearm-relative pelvic ring injuries, operative debridement and prophylactic antibiotics should be performed as indicated earlier. The decision to perform stabilization of the pelvic ring injury is controversial because the fracture pattern and resultant instability caused by a traversing bullet are often different from those caused by nonfirearm blunt trauma. A recent review of 86 patients with pelvic ballistic injuries investigated both treatment patterns and injury profiles.[39] They reported 9.3% of patients underwent a surgical debridement; however, no firearm-related pelvic fractures required surgical stabilization.

Skeletal Stabilization

Skeletal stabilization has been shown to be crucial for soft tissue healing, especially in the setting of an open fracture. Compared with casts and splints, internal and external fixation permit greater access for wound care and are more effective in controlling pain during mobilization. In general, the decision to use one mode of fixation over another is dependent on the fracture pattern and associated soft tissue injuries, the degree of contamination, and the overall clinical status of the patient at the time of surgery. If a clean soft tissue envelope can be achieved at the index operation, definitive fracture fixation through open reduction internal fixation (i.e., plating) or intramedullary nailing are both acceptable options and can result in good outcomes. However, assessment of the soft tissue envelope and its cleanliness with regard to both timing and method of definitive fixation is at the discretion of the treating surgeon.

In hemodynamically unstable patients or those with grossly contaminated wounds, standard or ringed external fixation devices can be used for both temporary stabilization and definitive fixation. External fixators can be applied relatively quickly with minimal soft tissue dissection and avoid the application of surface implants in wounds with concern for contamination or infection. They can be easily removed, replaced, and adjusted and can also be combined with other means of fixation when indicated. However, external fixators are not without their problems. The most common complication of external fixators is superficial pin tract infections, which can often be treated successfully with local pin-site care and oral antibiotics. Pin track osteomyelitis is a relatively rare complication with modern surgical techniques; however, its risk is not zero, particularly in poor hosts or settings in which the external fixator remains in place for multiple weeks or months. Their use can be effective in temporary stabilization of severe soft tissue wounds that require soft tissue coverage, but location of the pins and bars can make subsequent debridement and reconstructive procedures cumbersome. Periarticular and more extensive fracture patterns may require the application of Ilizarov circular external fixators, which can further limit access. Although effective in providing temporary skeletal stabilization during repeat debridement and soft tissue reconstruction, external fixation is not ideal for achieving fracture union, and additional surgical procedures, such as conversion to internal fixation with or without bone grafting, are often necessary.

Intramedullary nailing of open fractures at the time of the initial operation has become a standard treatment option in recent decades. Historically, open fractures (e.g., tibia shaft fractures) were initially stabilized with external fixators until a stable and clean soft tissue bed could be achieved, at which point the external fixator was removed and definitive implants were placed. Acute intramedullary nailing of open fractures has gained popularity, and multiple meta-analyses have supported their use in treating open fractures.[40] A more recent meta-analysis of 12 randomized controlled trials that included 1090 patients compared outcomes of definitive fixation of open tibia shaft fractures with external fixation versus intramedullary nailing.[41] The authors reported no difference in rates of deep infection, nonunion, delayed union, or implant failure between groups and also observed higher incidence of superficial infection, pin-tract infection, and malunion in the external fixation group. This led the authors to conclude that intramedullary nailing is advantageous and supported its use over external fixation for definitive fixation.[41] The consideration between reamed and unreamed intramedullary nailing has also been extensively studied, with most authors reporting benefit to reamed nailing with lower rates of nonunion, implant failure, and reoperations.

ACUTE COMPARTMENT SYNDROME

Acute compartment syndrome can be a devastating condition for patients, developing from a variety of injuries and medical conditions, and has become a common source of medical litigation. Early recognition and treatment of compartment syndrome is critical to decrease the risk of limb dysfunction, amputation, and in some cases death. The most common etiologies include fractures (open and closed), soft tissue injury without fracture, patients on anticoagulants or with bleeding disorders, drug overdoses, circumferential burns, vascular injuries, crush injuries, reperfusion injuries, ballistic injuries, and tight circumferential dressings or casts. Although uncommon, it can develop during surgery, including patient positioning during surgery such as the lithotomy position with prolonged flexion, elevation, and abduction of the well leg during an operation. Elevations in compartment pressures have also been reported during intramedullary nailing of tibia shaft fractures; however, the pressure changes are generally transient and eventually return to baseline.

A 19th-century German doctor, Richard von Volkmann, was among the first to describe the sequelae of postischemic contracture (known as *Volkmann ischemic contracture*), which he attributed to trauma, swelling, and tight bandaging. These contractures were often due to missed compartment syndromes. Classically, this condition was associated with a supracondylar humerus fracture leading to forearm ischemia from acute compartment syndrome. As late complications of compartment syndrome, such as Volkmann ischemic contracture, of the upper and lower extremities have been elucidated, the importance of early recognition and fasciotomy has become paramount. Missed or delayed diagnosis and prompt treatment of this condition has resulted in numerous cases of preventable morbidity and rare cases of mortality and is one of the most common causes of malpractice litigation for orthopedic surgeons. The etiologies are many, but this section will primarily address the pathogenesis, diagnosis, and management of acute compartment syndrome, specifically in the forearm and lower leg.

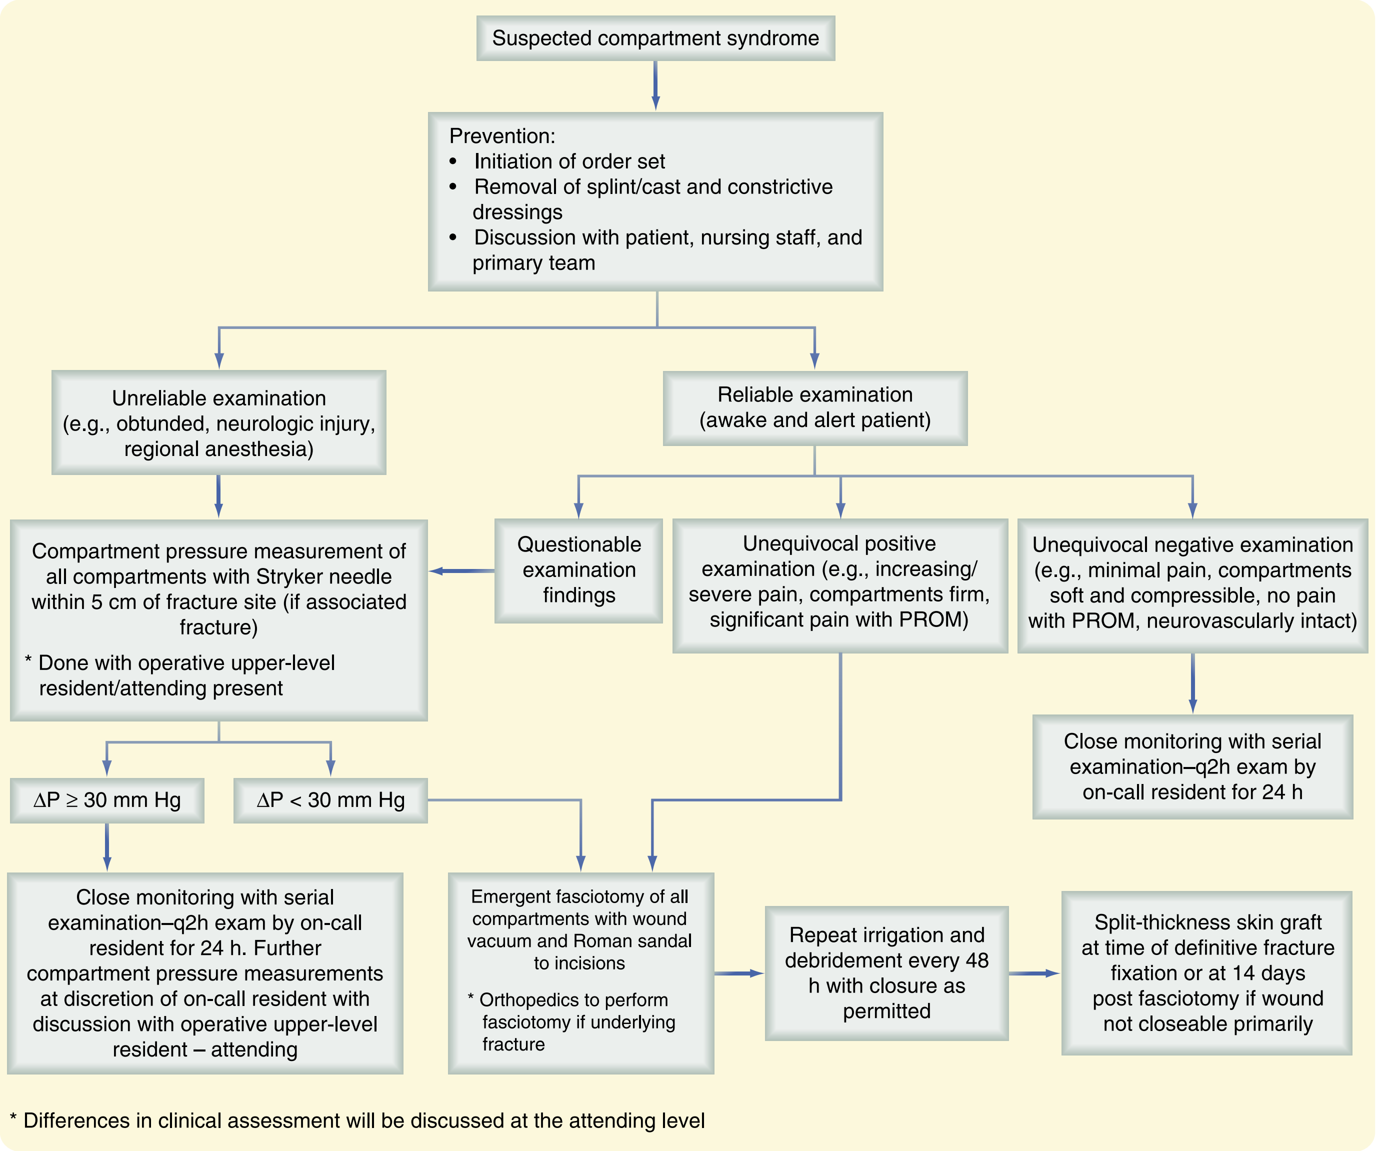
Pathogenesis

The pathophysiologic mechanism underlying the development of acute compartment syndrome is decreased intracompartmental space or increased intracompartmental fluid volume leading to increased pressure within the compartment. In general, compartments are separated by their own fascia, which is a thin, inelastic form of connective tissue that surrounds muscle compartments and limits its ability to expand. Increased pressure within the compartment leads to hemodynamic disruption within the compartment and reduction of venous outflow. As arterial inflow remains undisrupted, at least initially, blood continues to flow in but cannot flow out, which results in increased venous pressure and a local arteriovenous gradient that does not allow sufficient blood flow to meet the metabolic demands of the tissue. Eventually, pressures may increase high enough to disrupt arterial inflow leading to decreased oxygenation of the tissues, ischemia, and eventual irreversible tissue necrosis. When muscle tissue is deprived of oxygen, inflammatory cytokines are released that increase capillary permeability producing additional swelling and further elevating compartment pressure. Muscle ischemia also leads to the release of myoglobin and other inflammatory and toxic metabolites into circulation, which can result in renal failure, shock, and cardiac arrhythmias. As such, this pathologic process is difficult to reverse once it has begun, and the only treatment is release of the fascial tissues to allow additional room for the swelling.

Diagnosis

The diagnosis of compartment syndrome requires a high degree of clinical suspicion; performing serial examinations in high-risk patients is essential, with well-documented changes in physical examination over time indicating compartment syndrome. Patient history and mechanism of injury are also important in identifying at-risk patients. Although general understanding of the existence and implications of compartment syndrome is common among providers, no clear definition of when it is present exists. Institutional protocols for diagnosis and management of compartment syndrome have been developed as part of a multidisciplinary collaboration, and an example is illustrated in Fig. 40.22. Historically, the clinical diagnosis included presence of the 6 Ps: pain out of proportion, pressure or firmness of the compartment, pulselessness, paralysis, paresthesia, and pallor. More commonly accepted clinical signs of compartment syndrome include those of pain that is out of proportion from what is expected from a particular injury (one of the earliest and most sensitive signs), pain with passive stretch of involved muscle groups, and paresthesia in the distribution of sensory nerves located within the compartment. However, previous studies have found the clinical signs and symptoms of compartment syndrome have low sensitivity, and furthermore, these signs can also be found in patients without compartment syndrome. Pain may even be absent in a patient with acute compartment syndrome, often as the result of a superimposed central or peripheral neurologic deficit, or in an obtunded patient who cannot provide a reliable examination.

Whenever a clinical examination is not reliable, measurement of compartment pressures is highly recommended, and this can be performed serially over time or continuously depending on the resources available to you. Some authors have recommended routine measurement of pressures in all patients, yet more recent studies have found the need for pressure monitoring to be controversial, and some have even refuted its value. This was exemplified in a previous study that closely followed compartment and blood pressure measurements in 19 patients with lower extremity fractures who did not have clinical criteria diagnostic for compartment syndrome.[42] They observed 84% of patients to have at least one compartment measurement that equated with a perfusion pressure less than 30 mm Hg, which is a diagnostic criterion and represents the difference between the measured compartment pressure and concomitant diastolic blood pressure. More recent studies have suggested that continuous pressure monitoring should be the gold standard for diagnosis and recommended using a perfusion pressure threshold of 30 mm Hg that is present over 2 consecutive hours or more, which demonstrated a 94% sensitivity for diagnosis of acute compartment syndrome.[43]



Suspected compartment syndrome
Prevention:
• Initiation of order set
• Removal of splint/cast and constrictive dressings
• Discussion with patient, nursing staff, and primary team
Unreliable examination (e.g., obtunded, neurologic injury, regional anesthesia)
Reliable examination (awake and alert patient)
Compartment pressure measurement of all compartments with Stryker needle within 5 cm of fracture site (if associated fracture)
* Done with operative upper-level resident/attending present
Questionable examination findings
Unequivocal positive examination (e.g., increasing/ severe pain, compartments firm, significant pain with PROM)
Unequivocal negative examination (e.g., minimal pain, compartments soft and compressible, no pain with PROM, neurovascularly intact)
Close monitoring with serial examination–q2h exam by on-call resident for 24 h
ΔP ≥ 30 mm Hg
ΔP < 30 mm Hg
Close monitoring with serial examination–q2h exam by on-call resident for 24 h. Further compartment pressure measurements at discretion of on-call resident with discussion with operative upper-level resident – attending
Emergent fasciotomy of all compartments with wound vacuum and Roman sandal to incisions
* Orthopedics to perform fasciotomy if underlying fracture
Repeat irrigation and debridement every 48 h with closure as permitted
Split-thickness skin graft at time of definitive fracture fixation or at 14 days post fasciotomy if wound not closeable primarily
* Differences in clinical assessment will be discussed at the attending level

FIGURE 40.22 Algorithm for the management of a patient with suspected compartment syndrome. *PROM*, Passive range of motion.

Potential shortcomings should be considered when using compartment pressure measurements for decision-making and diagnosis. Pressure measurements should be taken using a side-port needle and a pressure measurement system. The most common method of measurement is the Stryker Intra-Compartmental Pressure Monitor System (STIC; Stryker, Mahwah, NJ), which uses the side-port needle technique (Fig. 40.23). Alternative measurement systems include a wick or slit catheter or an arterial line setup. Slit catheters can be used in continuous monitoring systems, and although arterial line setups are widely available, they tend to artificially elevate pressure measurements. Second, the location of the pressure measurement within a given muscle compartment has been shown to affect results. Pressures obtained within 5 cm of a fracture are the highest, and pressures measured more centrally within a muscle are generally higher than those obtained peripherally. It is suggested that obtaining measurements farther away from the zone of injury is more representative of the entire compartment; however, no formal consensus of this has been established. Technique used when measuring pressures can also introduce variability in pressure values. A previous cadaveric study demonstrated significant variability in measurement technique, and with a known compartment pressure before measurements, only 60% of measurements were within 5 mm Hg of the known compartment pressure. Finally, calculation of the perfusion pressure is

highly dependent on timing of the measurement, and this was demonstrated in a previous study that recorded preoperative, intraoperative, and postoperative blood pressures in patients undergoing intramedullary nailing of tibia fractures. The authors observed lower intraoperative diastolic blood pressures while the patient was under general anesthesia, leading to significantly lower perfusion pressure calculations that could result in unnecessary fasciotomies. Thus, they recommended use of the preoperative diastolic blood pressures when calculating perfusion pressures. Current research is investigating other modalities to improve the diagnosis of acute compartment syndrome, such as using biomarker measurements of pH and intramuscular glucose to identify patients with impaired muscle metabolism.

Surgical Treatment

The treatment for acute compartment syndrome is immediate surgical fasciotomy, which can be performed through various surgical techniques. Release of the skin and fascia effectively increases the volume of the muscle compartment, thereby resulting in an immediate reduction in the compartment pressures. It is critical that this be done before the onset of irreversible tissue necrosis because of the potential complications, systemic risks, and morbidity of delayed fasciotomy. The efficacy of early fasciotomy has been documented in several previous studies, and some authors have even suggested that performing an unnecessary fasciotomy is better than performing one too late. Nonetheless, surgical fasciotomy is not without complications, as it is generally associated with delayed wound closure or skin grafting, nerve injury, muscle weakness, chronic venous insufficiency, cosmetic problems, and chronic pain. It has been shown to increase costs of care through longer hospital stays, increased rates of infection, and increased rates of delayed union and nonunion.

When performing fasciotomies in the lower leg, the surgeon may choose a single- or two-incision approach. The two-incision, four-compartment fasciotomy is the most widely used technique and allows for easy access to all four compartments of the leg. This approach involves making an anterolateral incision centered halfway between the tibia and fibula and a posteromedial incision just posterior to the medial border of the tibia (Fig. 40.24). Once the fascia is identified through the lateral incision, the intermuscular septum separating the anterior and lateral compartments can be visualized. The posteromedial incision is made approximately 2 cm posterior to the medial border of the tibia to obtain access to the superficial and deep posterior compartments. Through both incisions, the individual compartments can then be completely released under direct visualization; to release the deep posterior compartment, the soleus must be released from the posteromedial corner of the tibia. Extreme care must be taken to identify, protect, and avoid injury to the superficial peroneal nerve, which can be seen within the lateral compartment through the anterolateral incision, and the saphenous vein and nerve running superficially through the posteromedial incision. Alternatively, a single-incision, four-compartment fasciotomy can be performed through a parafibular posterolateral skin incision, and this has also been shown to provide a highly effective means of decompression of all four compartments.

It is generally recommended that incisions not be closed primarily at the time of fasciotomy because skin closure may lead to unintended reelevation of compartment pressures by allowing less space for expansion of swollen tissues. The fasciotomy wounds are generally dressed with either a negative-pressure wound vacuum or wet-to-dry dressings, depending on surgeon preference. Negative-pressure dressings reduce swelling through removal of excess fluid from the tissues, which may aid in staged primary skin closure. Repeat irrigation and debridement of the fasciotomy incisions and necrotic tissue should be performed every 2 to 3 days, and attempts at early or delayed primary skin closure can be attempted. Numerous adjunctive wound closure techniques have been described to aid in this process, including gradual suture approximation, the "shoelace technique" with tensioned vessel loops through staples at the skin edges, vacuum-assisted closure, and dynamic dermatotraction devices. If a tension-free closure is not possible, the exposed muscle can be covered with a split-thickness skin graft.

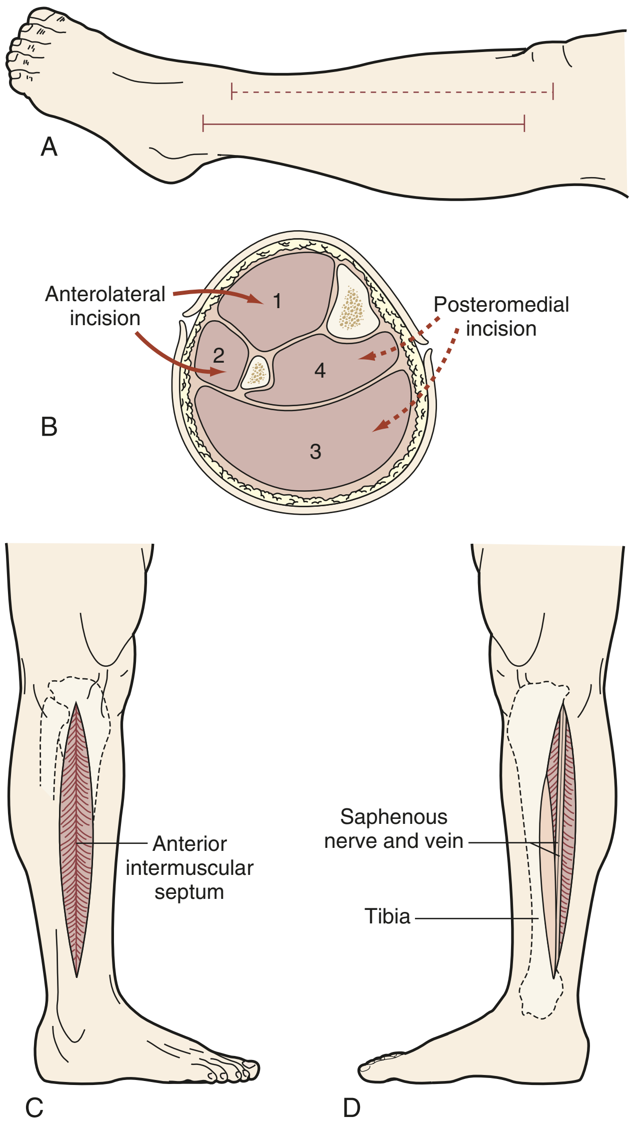

FIGURE 40.24 (A) Double-incision technique for performing fasciotomies of all four compartments of the lower extremity. (B) Cross-section of the lower extremity showing positions of anterolateral and posteromedial incisions that allow access to the anterior and lateral compartments (*1* and *2*) and the superficial and deep posterior compartments (*3* and *4*). (C) The anterior intramuscular septum should be identified in the lateral incision, as it marks the division of the anterior and lateral leg compartments. (D) The saphenous nerve and vein are identified in the medial incision and should be protected during compartment release.

PELVIC RING INJURIES

The overall incidence of pelvic ring injuries is approximately 37 per 100,000 people per year across the United States. Pelvic ring injuries are a major cause of patient morbidity and mortality, and they may present in a wide spectrum of injury depending on patient age, bone quality, and mechanism of injury. Low-energy ground-level falls in elderly patients may simply result in a pubic ramus fracture, whereas high-energy motor vehicle accidents in younger patients may present with a significantly unstable injury pattern with life-threatening hemorrhage. It has been reported that up to 80% of these patients also have additional MSK injuries, and mortality rates vary from 15% to 25% depending on the severity and number of associated injuries. Because of the high-energy nature of these injuries, they are often associated with other non-MSK injuries, such as concomitant chest trauma, head injuries, visceral organ damage, and genitourinary injuries. Higher Injury Severity Scores (ISS) scores, shock on arrival, greater transfusion requirements, and patient age are risk factors for mortality in patients with pelvic ring fractures, and risk of mortality increases almost thirteenfold when the patient is hypotensive. In combination with a head or abdominal injury that requires surgical intervention or if the pelvis fracture is open, mortality increases to 50%. When both procedures are necessary, mortality approaches 90%. Routine ATLS protocols should be enacted in the initial workup and evaluation of these patients, and this should include a rectal/vaginal examination and assessment of open perineal wounds as part of the physical examination. Long-term disability, such as low back or pelvic pain, leg length discrepancies, dyspareunia, difficulty with childbearing, impotence, and incontinence, may result as sequelae from the injury itself and/or from nonanatomic reduction of the pelvic ring. Furthermore, even with successful restoration of the anatomy, patients can have long-term disability from the associated genitourinary and neurologic injuries affecting the lower extremity.

Classification

Pelvic ring injuries present with a wide spectrum of levels of instability. From an osseous standpoint, the pelvic ring is composed of the sacrum and bilateral innominate bones (includes an ilium, ischium, and pubis). In isolation, the bony pelvis has no inherent stability, but rather, through several strong ligamentous and soft tissue attachments, the pelvic ring is able to maintain its shape and withstand physiologic forces without deformation (Fig. 40.25). There are multiple previously described classification systems for pelvic ring injuries, and the two most common are the Tile classification and Young and Burgess classification schemes. The Tile classification categorizes injuries into three types, and each differs by its spectrum and direction of stability. Type A injuries are considered stable (e.g., avulsion injuries), type B are considered rotationally unstable but vertically stable (e.g., pubic symphysis disruption), and type C are considered rotationally and vertically unstable (e.g., vertical shear injury) (Fig. 40.26).

The Young and Burgess system classifies injuries mechanistically, with fracture patterns correlating with the direction of the applied energy at the time of the trauma. This is the most commonly used system for classification and is useful in guiding treatment decision-making. The system is composed of anterior-to-posterior compression (APC) injuries, lateral compression (LC) injuries, and vertical shear (VS) injuries (Fig. 40.27). In general, APC injuries have the greatest risk for retroperitoneal hemorrhage, and APC III patterns result in a significant increase in the intrapelvic volume and potential space for blood loss (Fig. 40.28). APC III injuries have the highest rate of mortality, blood loss, and need for transfusion among all pelvic ring injuries.

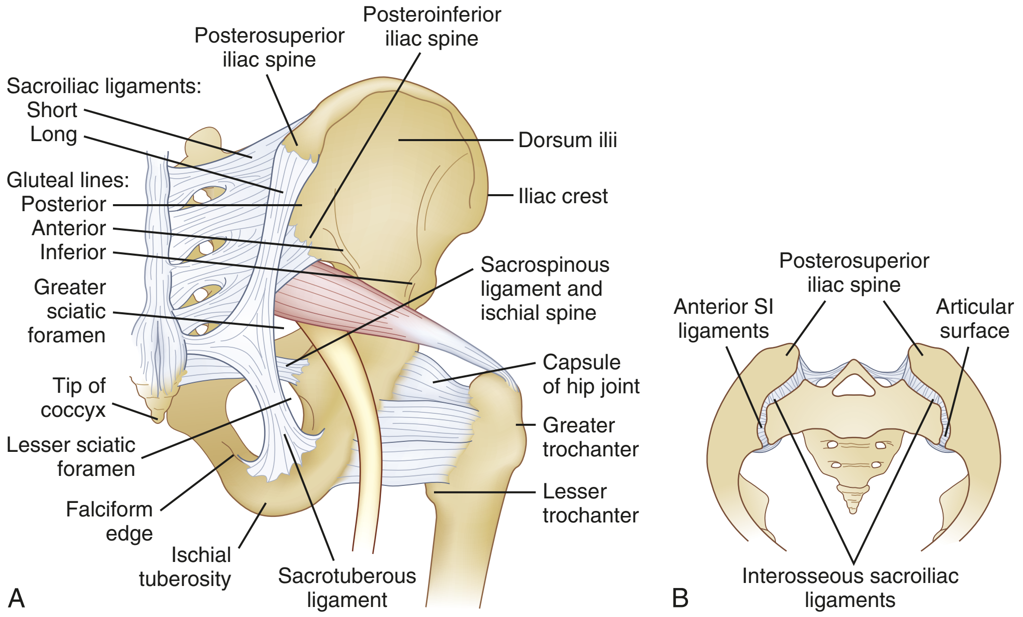

FIGURE 40.25 Ligamentous complexes of the pelvis. (A) Posteriorly, the major ligaments noted in the region of the sacroiliac (SI) joint are the posterior SI ligaments, both long and short. The long ligaments blend with the sacrospinous and sacrotuberous ligaments. (B) In cross-section, the orientation of the very thick posterior interosseous SI ligaments is noted. (From Stover MD, Mayo KA, Kellam JF. Pelvic ring disruptions. In: Browner BD, Levine AM, Jupiter JB, et al., eds. *Skeletal Trauma: Basic Science, Management, and Reconstruction.* 4th ed. WB Saunders; 2008.)

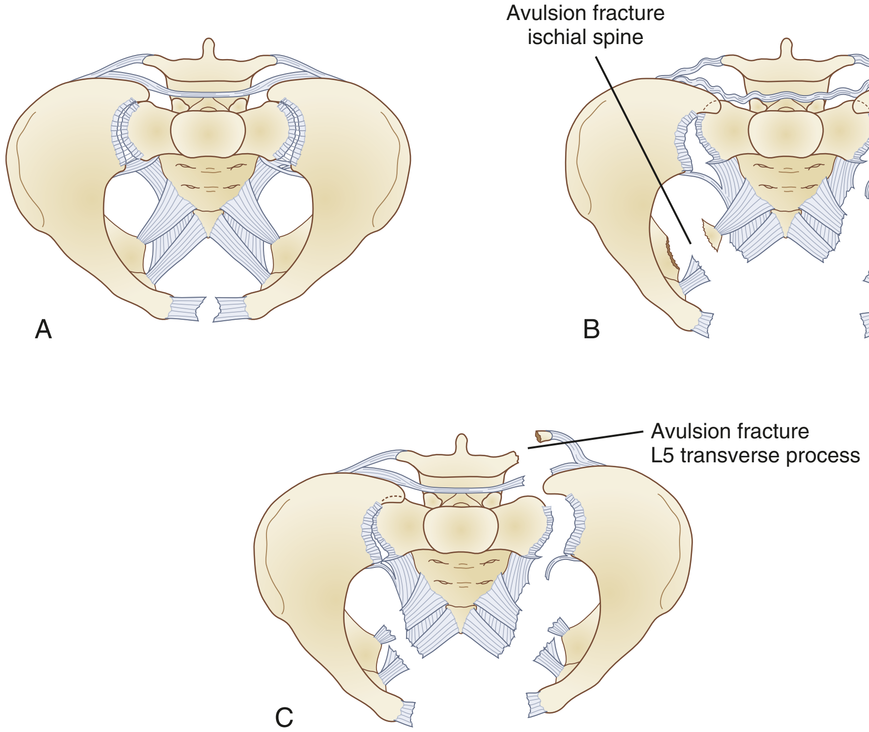

FIGURE 40.26 (A) Division of the symphysis pubis allows the pelvis to open to approximately 2.5 cm with no damage to any posterior ligamentous structures. (B) Division of the anterior sacroiliac and sacrospinous ligaments, either by direct division of their fibers *(right)* or by avulsion of the tip of the ischial spine *(left)*, allows the pelvis to rotate externally until the posterior superior iliac spines abut the sacrum. Note, however, that the posterior ligamentous structures (e.g., the posterior sacroiliac and iliolumbar ligaments) remain intact. Therefore, no displacement in the vertical plane is possible. (C) Division of the posterior band ligaments, that is, the posterior sacroiliac and the iliolumbar, causes complete instability of the hemipelvis. Note that global displacement is now possible. (From Stover MD, Mayo KA, Kellam JF. Pelvic ring disruptions. In: Browner BD, Levine AM, Jupiter JB, et al., eds. *Skeletal Trauma: Basic Science, Management, and Reconstruction.* 4th ed. WB Saunders; 2008.)

LC and VS fractures are more commonly associated with intraabdominal and head injuries, and the most common cause of death in a patient with an LC injury pattern is associated closed head trauma. There are a number of other pelvic ring injury classification systems such as the Denis classification of sacral fractures, Roy-Camille classification of spinopelvic dissociation, Isler classification of sacral fractures, and the Nakatani classification of pubic ramus fractures; however, they will not be discussed in depth here.

Finally, as discussed earlier, determination of the level of instability of the injured hemipelvis (or the entire pelvis) may be determined through classification systems based on imaging studies. The best imaging study to screen the presence of a pelvic fracture is a plain AP radiograph. Although it has been noted that placement of a sheet or binder could potentially obscure identification of these injuries, this lifesaving maneuver should be performed as early as possible when necessary for hemorrhage control. The x-ray will provide important information regarding the amount of instability and degree of initial displacement and greatly aids in the process of making immediate management decisions. The vast majority of trauma patients will undergo routine CT scans of the chest, abdomen, and pelvis as part of institutional protocols, and this will provide more detailed information on subtle injuries not appreciated on plain radiographs. If there is concern for a urethral injury or bladder injury, a retrograde urethrogram or cystogram may be obtained, respectively. The true amount of instability present in a pelvic ring injury cannot be fully understood on static imaging, and as a result some patients are taken to the operating room for a stress examination under anesthesia or have special stress radiographs ordered to more accurately identify the unstable patterns that will benefit most from surgical stabilization.

Initial Management and Resuscitation

Pelvic stabilization and control of hemorrhage are the goals of initial management of unstable pelvic ring injuries. There are a number of potential sources of bleeding in pelvic ring injuries, the most common being the presacral venous plexus within the pelvis, which often leads to the development of a retroperitoneal hematoma and can accommodate up to 4 L of blood. Other sources are bleeding from the fractured cancellous bony surfaces, nutrient arteries, and arterial injuries. The reported incidence of arterial bleeding in closed pelvic ring injuries is approximately 1 to 2 cases per 100,000 people per year. The superior gluteal artery is the most commonly injured vessel, but the obturator and pudendal vessels can also be involved depending on the location of fractures and the injury pattern.

If patients present with hemodynamic instability, it is important to have a high suspicion for pelvic bleeding as a potential source because in approximately 60% of those patients, the pelvis is the main source of blood loss. Therefore, the temporary initial treatment of pelvic ring injuries with volume expansion is to place

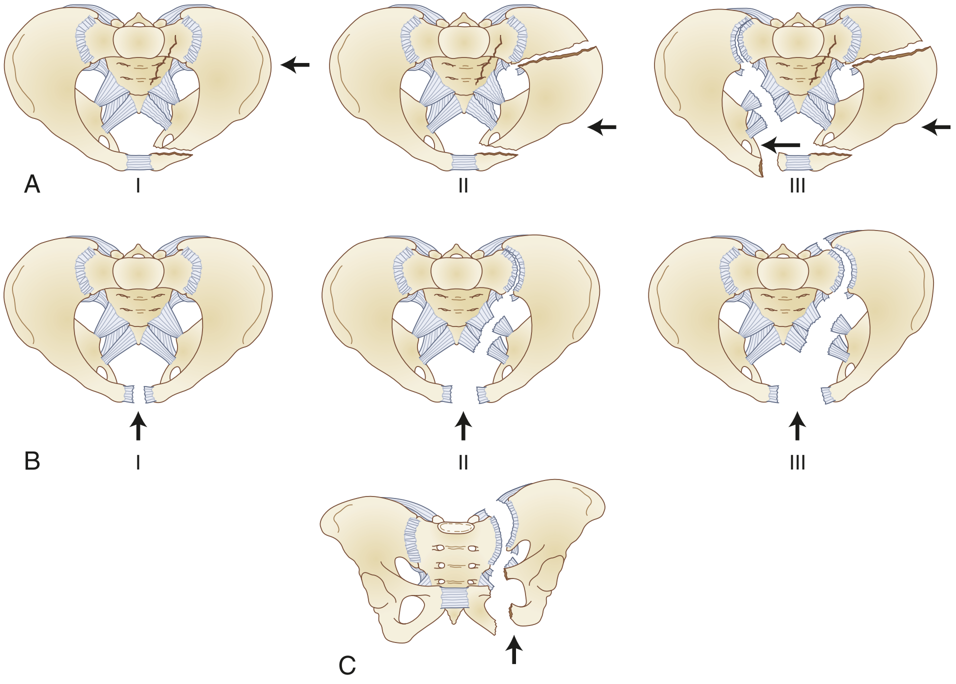

FIGURE 40.27 Young and Burgess classification. (A) Lateral compression force. Type I, a posteriorly directed force causing a sacral crushing injury and horizontal pubic ramus fractures ipsilaterally. This injury is stable. Type II, a more anteriorly directed force causing horizontal pubic ramus fractures with an anterior sacral crushing injury and either disruption of the posterior sacroiliac joints or fractures through the iliac wing. This injury is ipsilateral. Type III, an anteriorly directed force that is continued and leads to a type I or type II ipsilateral fracture with an external rotation component to the contralateral side; the sacroiliac joint is opened posteriorly, and the sacrotuberous and spinous ligaments are disrupted. (B) Anteroposterior compression fractures. Type I, an anteroposterior-directed force opening the pelvis but with the posterior ligamentous structures intact. This injury is stable. Type II, continuation of a type I fracture with disruption of the sacrospinous and potentially the sacrotuberous ligaments and an anterior sacroiliac joint opening. This fracture is rotationally unstable. Type III, a completely unstable or vertical instability pattern with complete disruption of all ligamentous supporting structures. (C) A vertically directed force at right angles to the supporting structures of the pelvis leading to vertical fractures in the rami and disruption of all the ligamentous structures. This injury is equivalent to an anteroposterior type III or a completely unstable and rotationally unstable fracture. (Adapted from Young JWR, Burgess AR. *Radiologic Management of Pelvic Ring Fractures*. Urban and Schwarzenberg; 1987.)

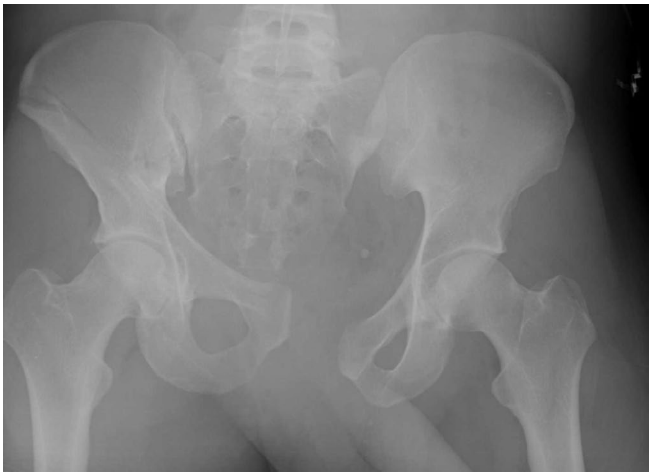

FIGURE 40.28 Anteroposterior pelvic radiograph showing the anterior-to-posterior compression (or "open-book") pelvis. Complete disruption of the anterior and posterior ligamentous structures leaves this pelvis rotationally and vertically unstable.

a circumferential binder or sheet to stabilize the pelvic ring and decrease the volume within the pelvis (Fig. 40.29). To apply properly, the binder or sheet must be centered over the greater trochanters with the legs adducted and internally rotated and tightened at the level of the trochanters. One benefit of using a sheet instead of a binder is that holes can be cut for access during angiography and placement of percutaneous screws. The added stability allows for clot formation, reapposition of anatomic surfaces, and decreased hemorrhage for all fracture patterns. Although historically there was concern that binders or sheet use could lead to skin breakdown or pressure ulcers, the current consensus is that this is not a concern unless the patient does not receive attentive and frequent turning, which patients with pelvic fractures should undergo even before fixation.

In patients who remain hemodynamically unstable despite appropriate resuscitation measures and temporary stabilization, the possibility of arterial hemorrhage should be considered. A prospective study of 143 patients with high-energy pelvic fracture showed that 10% had arterial injury, and factors predictive of arterial bleeding included a base deficit of

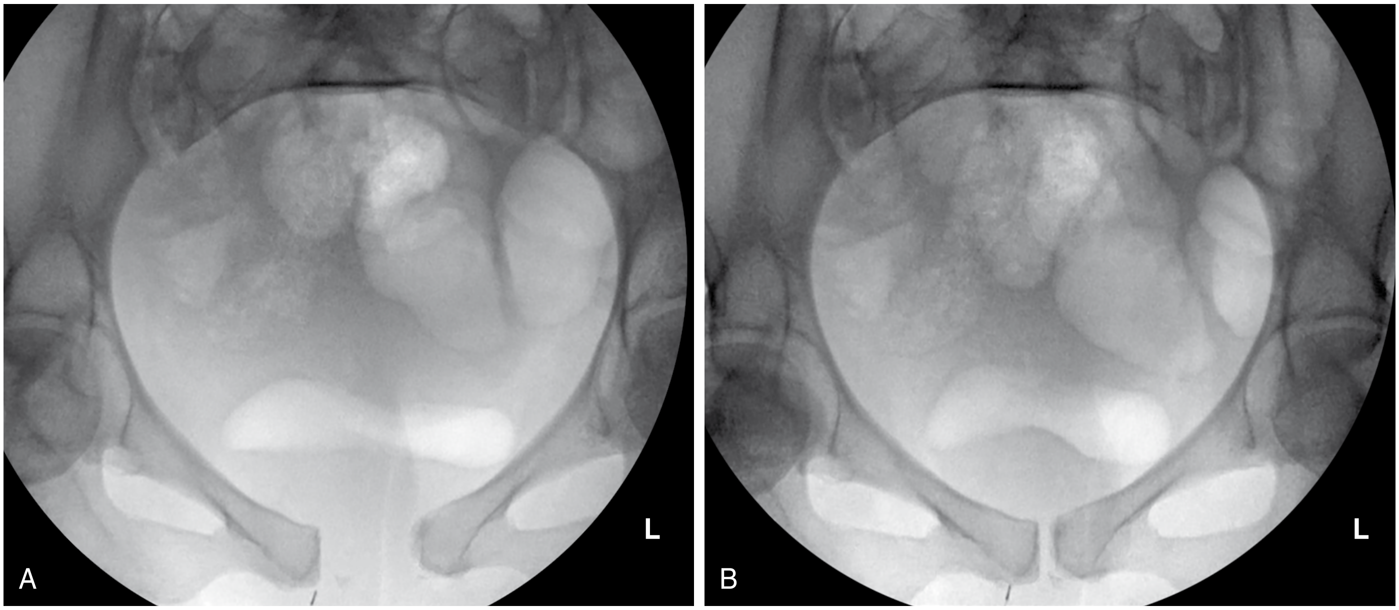

FIGURE 40.29 (A) Pelvic ring with bilateral anteroposterior compression and two injuries demonstrating widening of the pubic symphysis and bilateral anterior sacroiliac joints. (B) Internal rotation of the legs with compression on the greater trochanters bilaterally anatomically reduces the pelvic ring.

6 mmol/L, a systolic blood pressure less than 104 mm Hg, and the need for transfusion in the emergency department.[44] In many centers pelvic angiography with angioembolization is the gold standard for controlling pelvic arterial bleeding. This intervention is minimally invasive, effective, and specifically targeted to bleeding vessels. It is recommended that institutions have interventional radiologists readily available to perform these procedures when needed, no matter what time of day or night. It can be performed in either the internal iliac artery (nonselective) or distal to the internal iliac artery (selective). Although its benefit in pelvic fracture patients with hemodynamic instability is well documented, there are complication rates of 11%, including muscle necrosis, surgical wound breakdown, infection, and impotence. Complication rates are particularly high when associated with bilateral or nonselective pelvic angioembolization, which was demonstrated in one retrospective review that showed a 20% complication rate associated with nonselective angioembolization, so selective pelvic angioembolization is recommended when possible.[45]

If angioembolization is not an available resource, preperitoneal pelvic packing is an alternative technique. This may be effective in addressing venous bleeding, but it is less effective against arterial bleeding because some prior studies have reported up to 30% of patients still requiring angioembolization despite placement of packing. It also requires some degree of skeletal stabilization (pelvic external fixator or sheet/binder) in place to serve as a foundation to pack against and has higher reported rates of infection and complications. It is recommended that approximately six to nine laps are placed, starting posteriorly at the sacrum and moving anteriorly to the pubis. Packing should be removed after resuscitation in 24 to 48 hours, as delays in removal of the packing or repeat packing have been associated with increased infection rates. Ultimately, the decision to perform angioembolization versus preperitoneal pelvic packing is institutional specific, and timing of intervention requires a multidisciplinary treatment approach with the trauma surgeon, interventional radiologist, and orthopedic surgeon in order to improve outcomes, decrease time to intervention, and decrease complications.

Definitive Management

Definitive surgical stabilization of unstable pelvic ring injuries is dependent on the overall medical status and resuscitation of the patient and the planned treatment approach. Studies have demonstrated that early definitive fixation of pelvic ring injuries is both safe and effective, can be performed within 48 hours of injury, and will help to decrease complications and quicken recovery. In some cases, urgent percutaneous fixation strategies can be used to provide definitive internal fixation, such as placement of percutaneous screws. Pelvic external fixators can also be placed temporarily, usually during a concomitant surgery with the trauma team, and then later removed before definitive fixation after the patient has been resuscitated. There are certain circumstances in which an anterior pelvic external fixator is used definitively, and examples may include patients with open or contaminated anterior wounds, complex anterior ring fracture patterns, or bony anatomy that is not amenable to fixation with plates and/or screws. Patients with a large panniculus, associated open perineal wounds, or complex genitourinary tract injuries may also pose increased infection risks in the setting of internal instrumentation and would therefore be a poor candidate for open reduction and internal fixation. Patients who are otherwise good surgical candidates may undergo both open reduction and internal fixation or closed reduction with percutaneous screw fixation of their injuries at the discretion and comfort level of the surgeon. A detailed discussion of surgical approach and fixation techniques is beyond the scope of this text; however, examples of pelvic ring injuries and their definitive fixation constructs are displayed in Fig. 40.30.

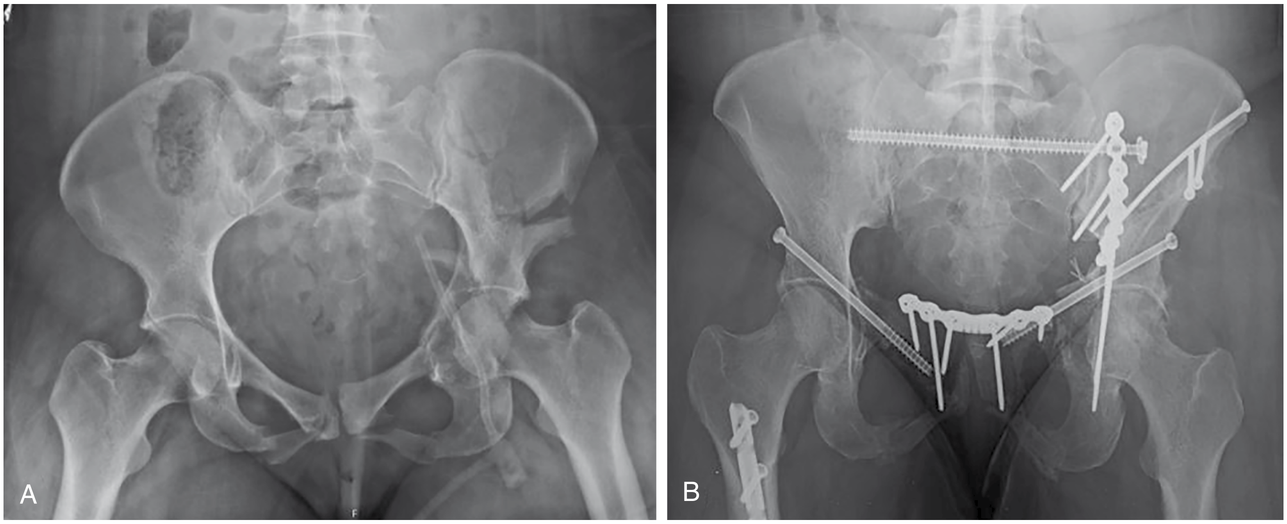

FIGURE 40.30 (A) Example of an unstable pelvic ring injury and (B) postoperative fixation construct.

DISLOCATIONS

Joint dislocations are generally considered an orthopedic emergency because of the increased risk of neurovascular injury and damage to the articular surface. Acute dislocations should be treated immediately because prolonged dislocation can lead to chondrocyte death, posttraumatic arthritis, joint ankylosis, and potentially avascular necrosis. Dislocations of major joints (e.g., shoulder, elbow, hip, knee, or ankle) are particularly concerning because of the high risk of neurovascular injury. Native joint dislocations are seen most commonly in young active patients as the result of a wide spectrum of injury mechanisms, and emergency department providers must be skilled in diagnosing and managing these injuries.

Patient Evaluation

It is important to immediately establish if this is a native versus prosthetic joint dislocation and whether it is an acute or chronic condition. A detailed patient history will help in providing information to answer those questions because some patients will have histories of recurrent dislocations or conditions that predispose them to dislocate with minimal trauma (e.g., recurrent shoulder dislocations in patients with hyperlaxity). The physical examination will include some common features across all joints, such as the joint's range of motion will be very limited and muscles surrounding the joint will be contracted. Completion of a thorough neurovascular examination is important, and certain neurovascular structures are known to be at risk with various dislocations that should be focused on (Table 40.6). Additionally, obtaining a baseline neurovascular examination before reduction will not only identify injuries present before the reduction (e.g., axillary nerve palsy in shoulder dislocation) but will also allow you to determine whether a neurovascular deficit improves after a reduction or gets worse. In some cases, a patient may not have a neurovascular deficit before a reduction but develops one afterward, and that is important to be aware of and document.

On examination the patient will commonly present with the dislocated joint in a pathognomonic position that will clue you into the most likely direction of the joint dislocation. For example, the majority of hip dislocations occur when the femoral head dislocates posteriorly relative to the acetabulum, and the patient will present with their leg flexed at the hip, internally rotated, adducted, and shortened. In the shoulder, the humeral head generally dislocates anterior to the glenoid, and the patient will present with their arm in an externally rotated and abducted position. In thin patients, there may be loss of the normal contour of the deltoid, the acromion is prominent posteriorly and laterally, and the humeral head itself may be palpable anteriorly.

Radiographs should be ordered initially to confirm the diagnosis and identify associated fractures. A high percentage of posterior hip dislocations have associated acetabular fractures (e.g., posterior wall acetabular fracture), and many shoulder dislocations will have impaction injuries to the humeral head (e.g., Hill Sachs lesion) or fractures of the glenoid rim (e.g., bony Bankart lesion). Standard orthogonal views are usually enough to establish

TABLE 40.6 Joint Dislocations and Commonly Associated Neurovascular Injuries

JOINT	STRUCTURE AT RISK	ASSOCIATED INJURIES OR LONG-TERM CONSEQUENCES
Hip	• Sciatic nerve • Femoral artery	• Common peroneal nerve palsy • Complete sciatic nerve palsy • Avascular necrosis of the femoral head • Posttraumatic arthritis
Knee	• Popliteal artery and vein • Common peroneal nerve	• Common peroneal nerve palsy • Popliteal artery and vein injury • Multiligamentous knee injury
Shoulder	• Axillary nerve • Axillary artery • Brachial plexus	• In patients <40 years old, labral tear • In patients >40 years old, rotator cuff tear
Elbow	• Brachial artery • Radial, ulnar, and median nerves	• Chronic instability • Stiffness • Posttraumatic arthritis • Heterotopic ossification

the direction of dislocation; however, as mentioned in the section on radiography, these must be true orthogonal images of the shoulder and not just internal and external rotation views of the proximal humerus.

Special Considerations for the Trauma Setting

Although all joint dislocations should be identified and reduced in a timely fashion, hip and knee dislocations require special consideration because of the potentially devastating consequences of delayed or missed diagnosis. Hip dislocations most commonly occur after high-energy motor vehicle crashes (46%–84% of reported dislocations), and this high level of energy often results in associated injuries to the femoral head, acetabulum, and soft tissues surrounding the hip. Sciatic nerve injuries are reported in 10% to 15% of posterior dislocations, with the peroneal branch most commonly affected because of the position of its fibers within the nerve and its tethering at the pelvis and fibular head. Anterior dislocations are more rare and have been associated with vascular injury to the common femoral artery and vein. Once an initial physical examination has been obtained to rule out both vascular and neurologic injury before any attempt at closed reduction is made and baseline imaging reviewed, a closed reduction under conscious sedation can be performed in an urgent manner. Previous studies have shown that delayed reduction may decrease the incidence of severity of nerve injury associated with dislocation, and additionally, delayed reduction is thought to decrease femoral head blood flow, increasing the risk of avascular necrosis. Several complications and morbidities have been reported after sustaining a hip dislocation, and those include posttraumatic arthritis (16%–24% of all hip dislocations), sciatic nerve palsy (10%–15%), avascular necrosis (6%–13%), and heterotopic ossification (2.8%–9%).[46]

Traumatic knee dislocations represent 0.02% to 0.2% of orthopedic injuries, approximately 0.5% of all major joint dislocations, and 40% to 64% are associated with vascular injuries, with the popliteal artery being the most commonly injured structure. Neurologic injuries are also associated with knee dislocations, and injury to the common peroneal nerve in particular has an incidence of 4.5% to 40% depending on the direction of the dislocation. These may present to the emergency department after having spontaneously reduced or still be dislocated. Similar to hip dislocations, they require a thorough neurovascular examination and imaging workup before reduction, but then should be reduced in an urgent fashion. They are also commonly associated with concomitant fractures of the proximal tibia, fibula, and sometimes the distal femur (Fig. 40.31). Vascular examination distal to the dislocation is critical, and pulses of the dorsal pedis and posterior tibia arteries should be assessed. This should be done through palpation, Doppler examination, and obtaining ABIs. If there are any signs of asymmetric or absent distal pulses, distal limb ischemia, or abnormal ABIs, one should have high suspicion for the presence of a vascular injury. Additional imaging in the form of CT angiography must then be considered, and if positive, vascular surgery should be consulted immediately. If the examination is otherwise negative for signs of vascular injury, patients should be braced and undergo serial examinations for up to 48 hours to monitor for an occult vascular injury.

Treatment

Once the initial physical examination and imaging workup are completed, the reduction should be urgently performed with some degree of sedation to aid in the reduction. The general reduction technique is to re-create the deforming force, apply traction, and then reverse the deforming force. For example, in a posterior hip dislocation, the position of the hip at the time of dislocation was most likely flexed, internally rotated, and adducted. When the hip dislocates, the femoral head usually rests on the posterior wall of the acetabulum, which inhibits reduction. Therefore, to reduce the joint, you must flex and internally rotate the hip and gently adduct to unhinge the femoral head from the posterior aspect of the acetabulum. Finally, axial traction will pull the femoral head anteriorly into the acetabulum and complete the reduction. Knee dislocations may be classified as medial, lateral, posterior, anterior, or rotatory, and this describes the position of the tibia relative to the distal femur. Anterior knee dislocations are the most common, with a reported incidence of approximately 40%. These can be reduced with axial traction and anterior translation of the femur. When a successful reduction is performed, the knee should be braced and a repeat neurovascular examination obtained and documented. Shoulder dislocations are treated in a similar fashion, and there are numerous well-described reduction maneuvers. The provider should choose whichever they are most comfortable with and trained in. If any joint dislocation is deemed irreducible after attempts at closed reduction with adequate sedation are made, the patient should be brought to the operating room for an attempt at closed reduction under general anesthesia and possible open reduction if indicated.

Finally, the majority of reduced joint dislocations should be immobilized using well-padded splints (e.g., elbow, wrist, and ankle) or joint-specific immobilizers (e.g., shoulder sling, knee immobilizer). All dislocations require either in-hospital or outpatient evaluation by an orthopedic surgeon.

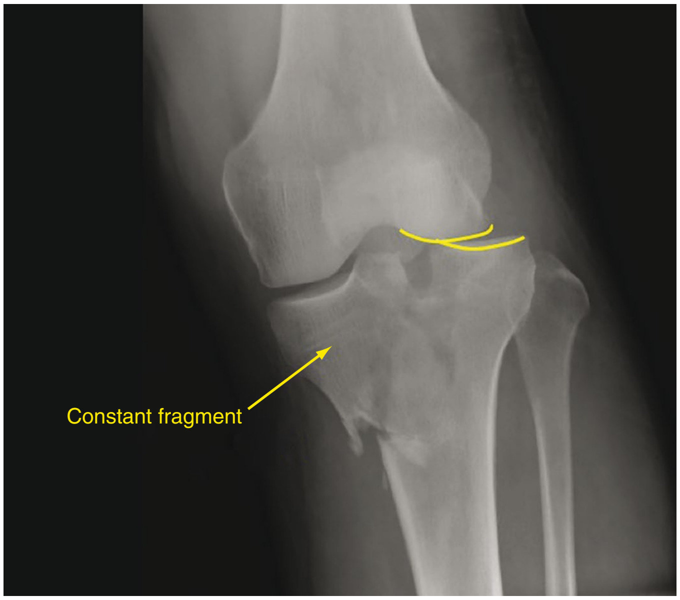

FIGURE 40.31 Medial tibial plateau fracture with a concomitant dislocation of the knee joint. Although it appears that the medial "constant fragment" is fractured off of the tibia shaft, this fractured fragment is maintaining its attachments to the distal femur. The tibia shaft is actually fractured off of the "constant fragment" and dislocated laterally. The incongruence of the lateral tibial plateau is noted.

VASCULAR AND MUSCULOSKELETAL INJURIES

Recognition

Prompt recognition of these injuries can be difficult because normal pulses are present in 5% to 15% of patients with a vascular injury, and overt hemorrhage causing obvious blood pressure changes is rare. Certain orthopedic injuries are known to be associated with vascular injuries and therefore should give the provider heightened suspicion, and these include knee dislocations and fracture dislocations, supracondylar humerus fractures, elbow dislocations, and unstable pelvic or acetabular fractures. However, certain findings on clinical examination, especially when compared with the unaffected limb, can have high sensitivity for early detection and diagnosis. These include pulselessness, pallor, paresthesia, paralysis, rapidly expanding hematomas, relative loss/decreased Doppler signals, obvious massive bleeding, and a palpable thrill or audible bruit. In lower extremity injuries, an ABI of less than 0.9 warrants further workup for vascular injury, and CT angiography is the recommended test of choice for diagnosis.

Management

A comprehensive description of surgical techniques for repair or reconstruction of vascular injuries is beyond the scope of this chapter. More relevant to this chapter are considerations specific to patients with concomitant orthopedic injuries that require skeletal stabilization either before or immediately after vascular repair. In general, skeletal stabilization should occur before vascular repair so that the manipulation performed during the reduction and skeletal stabilization does not endanger the repair. Additionally, temporary stabilization is typically recommended rather than definitive stabilization at the index procedure. Delaying vascular repair prolongs warm ischemia and tissue injury, so the patient may need a temporary shunt while the skeletal stabilization is performed before proceeding with the full vascular repair. Finally, concomitant fasciotomies (both prophylactic and postoperative therapeutic) should be considered in all patients who have had restored blood flow and have been associated with a significantly lower risk for amputation and other complications after limb revascularization.

COMMON LONG BONE FRACTURES

Femur Shaft Fractures

Epidemiology and Significance

The overall incidence of femoral shaft fractures ranges between 10 and 21 per 100,000 people per year across the world. They typically present in a bimodal distribution, with younger males (age 15–35 years) sustaining them from higher-energy injury mechanisms, and older females (age 60 years and older) sustaining them from lower-energy injury mechanisms. The most common cause is a motor vehicle crash, but they can also occur from falls from height, ground-level falls in the setting of osteoporosis, and ballistic injuries. Atypical fractures, such as those from bisphosphonate usage, occur from lower-energy mechanisms and have a reported incidence of 3.5% to 16% across studies. These trauma patients should be evaluated as part of the ATLS protocol to evaluate for other associated orthopedic injuries, in particular, ipsilateral femoral neck fractures and bilateral femoral shaft fractures. In patients with high-energy femoral shaft fractures (typically comminuted mid-to-distal shaft), there is a reported incidence between 2% and 9% of ipsilateral femoral neck fracture.[7–9] Because of its increased awareness, it is recommended that thin-cut high-resolution CT scan of the hip be ordered to assess for occult fracture. Bilateral femoral shaft fractures account for 2% to 7% of all femur fractures, are associated with high-energy injury mechanisms, can result in significant bleeding within the thigh, and therefore require more aggressive resuscitation. Providers should have a high index of suspicion for onset of systemic complications such as fat embolism syndrome (FES) and acute respiratory distress syndrome (ARDS) in these patients.

Initial Management

It is strongly recommended that femur shaft fractures be immobilized in some way before the patient is transported from the scene of the accident, and when performed by first responders, it generally includes placement in a traction splint. Without immobilization, displaced femoral shaft fractures will continue to cause increased pain, edema, bleeding, and potentially further damage to the surrounding soft tissues. Continued motion at the fracture site can also increase the risk of FES. Proper immobilization begins with in-line traction, which grossly restores length, alignment, and rotation, thereby decreasing the diameter of the thigh compartment and reducing its volume. The soft tissues are then under tension and can tamponade bleeding and facilitate clot formation at the fracture site. For patients in extremis, a posterior splint alone provides adequate immobilization until appropriate skeletal traction can be applied.

Definitive Stabilization

The recommended timing of definitive fixation of femoral shaft fractures has followed a parabolic course over the last few decades. In the 1970s, patients with a femoral shaft fracture were often thought of as being “too sick to operate on,” but this changed in the 1980s, as these patients were considered “too sick *not* to operate on.” Thus, there became a movement to operate on femoral shaft fractures within 24 hours after admission, and this treatment algorithm was termed *early total care (ETC).* In the 1990s, treatment algorithms and recommendations began to change, as pulmonary complications were shown to be more prevalent in patients who had both chest injuries and early femoral shaft fracture fixation. The reasoning behind these observations was that the systemic inflammatory system was primed after the initial injury, and the pulmonary load and subsequent inflammatory response of femoral nail insertion caused a “second-hit phenomenon” of hypoxemia and hypotension that led to the development of ARDS. This was the birth of damage control orthopedics (DCO).

DCO primarily consists of the placement of an external fixator on the femur to provide restoration of length, alignment, and rotation, as well as a closed reduction. The goals of DCO include provisional fracture fixation that allows mobilization of the patient, hemorrhage control, soft tissue management, and the prevention of the “second hit.” It is generally not recommended to definitively treat femoral shaft fractures in an external fixator because of high rates of loss of reduction, malunion, nonunion, and pin-site infections. Therefore, the external fixator is generally removed and definitive fixation (e.g., intramedullary nail) is placed once the patient is medically cleared for a second surgery.

Since the 1990s, the debate of DCO versus ETC has continued as our ability to more effectively resuscitate patients has improved. Multiply injured patients in extremis still benefit from DCO, and DCO is indicated in patients with persistent hypotension, metabolic acidosis, or a severe head injury but are otherwise going to the operating room for other urgent procedures. However, as new algorithms for determining clearance for surgery have been described, definitive treatment within the first 24 hours has become standard of care. Patients who are considered to be "borderline" are generally those with both soft organ and MSK injuries. Since the 1990s, multiple studies have disputed the idea that DCO is the best first-line treatment for borderline patients. When considering the incidence of ARDS, mortality, and length of stay, these studies have found either no difference between DCO and ETC or, if there was a difference in those end points, it was almost always in favor of ETC. Furthermore, the "borderline" patient is hemodynamically transient, but that patient frequently becomes "stable" within 24 hours of admission with appropriate resuscitation measures, especially with more liberal transfusion practices. Thus, many authors continue to advocate for definitive fixation of femoral shaft fractures in these patients within the first 24 to 48 hours, as multiple studies have shown it reduces the incidence of pulmonary complications, infections, and mortality.

Tibia Shaft Fractures

Epidemiology and Significance

The incidence of tibial shaft fracturs is approximately 16.9 per 100,000 people per year, and it tends to be more prevalent in males than in females (21.5 vs. 12.3 per 100,000). They generally occur in a bimodal distribution with regard to high- versus low-energy mechanism, and because of its subcutaneous location, these injuries are commonly open. High-energy mechanisms are commonly caused by direct trauma, resulting in short oblique or comminuted fractures with associated soft tissue injuries (e.g., open fracture), bone loss, compartment syndrome, and a fibula fracture at the same level. Low-energy injuries typically occur with indirect trauma or torsional forces that result in spiral fractures and often an associated fibula fracture at a different level.

Blood Supply

Tibial shaft fractures tend to be slow healing as a result of their tenuous blood supply and limited soft tissue envelope. A single nutrient artery that branches from the posterior tibial artery (distal continuation of the popliteal artery) supplies blood to the entire diaphysis. It enters the medullary canal and travels proximally and distally to anastomose with metaphyseal endosteal vessels. Although there is some contribution from the penetrating branches of the periosteal arteries that supply the outer third of the cortex, a diaphyseal fracture can easily compromise the nutrient arterial blood supply. Concomitant soft tissue stripping may leave an entire segment of tibia devascularized, and as a result, tibial shaft fractures are anatomically predisposed to impaired or prolonged healing and, with open fractures, to nonunion and infection.

Associated Soft Tissue Injuries

A comprehensive neurovascular examination should be performed to assess and document the status of the dorsal pedis and posterior tibial pulses. The soft tissues should be carefully evaluated for any signs or symptoms of compartment syndrome, open fractures, or fracture blisters. The incidence of compartment syndrome in tibial shaft fractures has been reported as high as 10%, so serial monitoring of the patient's signs and symptoms and, if necessary, compartment pressures is important. Neurovascular injury should be carefully evaluated for, as several structures traversing the lower leg may be injured by the initial trauma or subsequently became entrapped within the fracture site. Several previous case reports have documented entrapment of neurovascular and tendonous structures within fracture sites, impeding reduction, and so the provider should have a high index of suspicion for this when an appropriate reduction is unable to be achieved or if the neurovascular examination worsens after a reduction is performed.

Neurologic examination includes assessment of all five major nerves that traverse the lower leg to supply motor and sensory input to the muscles and overlying skin. The deep peroneal nerve, traveling in the anterior compartment, can be evaluated by testing first dorsal web space sensation as well as the patient's ability to extend the greater toe or dorsiflex the ankle. Testing of sensation on the dorsum of the midfoot and eversion strength will assess the superficial peroneal nerve, which travels in the lateral compartment. The tibial nerve travels in the deep posterior compartment and provides sensation to the plantar aspect of the foot and motor control of ankle and toe plantarflexion. The sural and saphenous nerves travel superficially to the fascia and are both pure sensory nerves. The sural nerve supplies sensation to the lateral aspect of the heel and midfoot, and the saphenous nerve supplies sensation to the medial ankle and hindfoot.

Management and Treatment

The definitive management of tibial shaft fractures may be operative or nonoperative. A closed fracture with minimal displacement and alignment that falls within the acceptable parameters of alignment (i.e., <5 degrees of varus/valgus, <10 degrees of anterior/posterior angulation, <1 cm of shortening, and >50% cortical apposition) can be treated by cast immobilization and later transition to functional bracing. However, the negative to nonoperative treatment is that patients must remain non–weight-bearing for an extended period of time, which is something not all patients may be able to comply with. Operative fixation with intramedullary nailing, which is the most common and preferred method of treatment, will allow the patient to begin weight-bearing immediately with therapy. Open reduction and internal fixation with plating can be considered for diaphyseal tibial fractures; however, it is more commonly used when the fracture extends proximally into the articular surface, distally into the metaphysis, or in patterns not amenable to intramedullary nailing with modern implants. To circumvent the need for large surgical incisions and soft tissue dissection around the fracture site, minimally invasive percutaneous plating techniques have been developed and lead to good outcomes. Historically, external fixation has been used as a definitive means of tibial shaft fracture fixation; however, it is more often used in patients who are too unstable for intramedullary nailing (i.e., DCO) or have severe soft tissue injuries that will require multiple debridements with possible soft tissue coverage. In these cases, the external fixation device will generally be removed and an intramedullary nail placed for definitive fixation once the patient has stabilized or when the soft tissues have stabilized and are appropriate for coverage.

Humerus Shaft Fractures

Epidemiology, Acceptable Alignment, and Associated Injuries

Fractures of the humeral shaft account for approximately 3% of all fractures and have an incidence of 13 per 100,000 people each year. They generally occur in a bimodal distribution with peak incidence in young males (age 21–30 years) after high-energy trauma and older females (age 60–80 years) after low-energy trauma. Historically, nonoperative treatment with bracing has been the treatment of choice, with studies reporting a nearly 95% rate of union and 85% return to full shoulder and elbow function after nonoperative treatment with a functional (Sarmiento) brace. If humeral shaft fractures can be maintained in acceptable alignment with nonoperative treatment, satisfactory outcomes can be achieved with minimal functional deficits. The parameters defining acceptable alignment include <20 degrees of sagittal plane deformity, <30 degrees of coronal plane deformity, and <3 cm of shortening. However, in recent years operative treatment has become more common with the advent of new operative techniques and implants, and several high-level systematic reviews have focused on the comparison of treatment methods. Overall, operative interventions have demonstrated lower rates of reoperation but higher rates of transient radial nerve palsy, whereas nonoperative treatment with functional bracing has demonstrated higher rates of nonunion and malunion requiring revision operations.

Radial nerve injuries occur in up to 6% to 18% of closed mid- and distal-third fractures at presentation (Fig. 40.32), and reported rates of postoperative radial nerve palsy range from 3% to 7%. The radial nerve is at risk of injury because of its close relationship with the humeral shaft as it travels from medial to lateral in the spiral groove, entering about 20 cm proximal to the medial epicondyle and exiting 14 cm proximal to the lateral epicondyle. In the setting of a closed fracture, treatment is generally nonoperative with observation for return of function over the subsequent months. In open fractures or ballistic injuries, the nerve is generally explored to assess whether or not it has been lacerated or transected by the initial injury, in which case the appropriate service is consulted for consideration of acute nerve repair versus delayed repair or grafting. When a radial nerve palsy is diagnosed on the initial physical examination, it is most commonly a neurapraxia and will recover spontaneously within 3 to 4 months in the majority of patients. The patient should be placed in a removable forearm splint during that time to support the wrist and fingers. If the nerve function does not return by 3 months, an electromyography can be ordered to determine if exploration is indicated. If a coaptation splint is placed and the patient develops a radial nerve palsy afterward, then the splint should be promptly removed. If the nerve function does not return after removal, then surgical exploration should be considered.

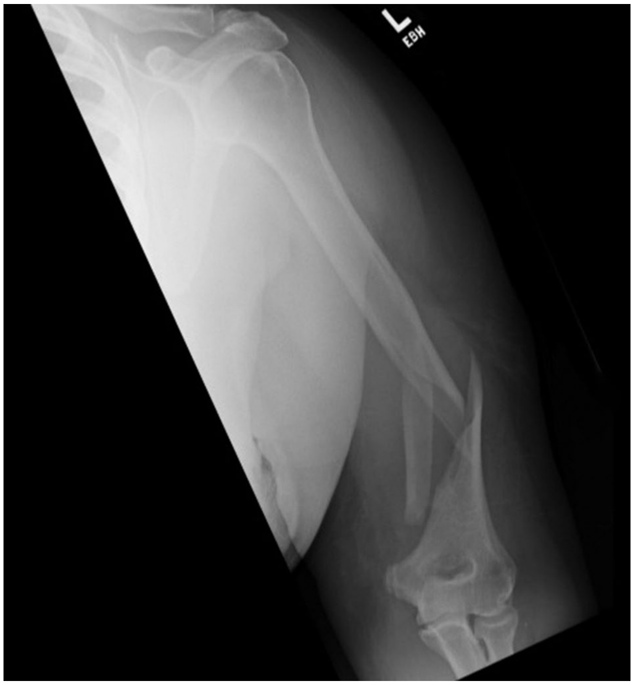

FIGURE 40.32 Holstein-Lewis fracture of the humeral shaft. This patient had no radial nerve function at presentation. At the time of surgery, the nerve was found to be intact but interposed between two fracture fragments. Full radial nerve function returned by 6 months.

Treatment

There are multiple nonoperative treatment methods: coaptation splints, hanging arm casts, “sling and swathe,” and functional bracing (i.e., Sarmiento). Although there are studies showing minor benefits to each method, the most common treatment is an initial coaptation splint followed by transition to a functional brace (Sarmiento brace) at clinic follow-up once swelling has decreased (usually 3–7 days later). Functional bracing is not initiated in the acute setting because it relies on the compression of soft tissues to exert a hydraulic, stabilizing force on the fracture; that pressure in the face of an acute injury can result in significant pain. During the functional brace stage, patients are allowed free elbow flexion-extension and arm abduction to 60 degrees, as motion will generate compressive forces from muscle contraction, helping to maintain alignment. However, potential complications of bracing include skin irritation, malunion, nonunion, and failure of nonoperative management requiring transition to operative treatment.

If a patient fails closed management, has an open fracture, has unstable fracture pattern (e.g., comminution, segmental), has an ipsilateral forearm or elbow fracture, or is a polytrauma patient who could benefit from earlier mobility to rehabilitate from other injuries, operative management should be considered. The mainstay of surgical management is compression plating for a transverse fracture pattern or lag screw compression and neutralization plating, and in some instances, an intramedullary nail may be used. An algorithm for decision of treatment is displayed in Fig. 40.33.

CHALLENGES AND COMPLICATIONS

Missed Injuries

The incidence of missed injuries after the primary and secondary surveys in trauma patients widely varies across studies and has been reported between 0.6% and 39%. MSK injuries, specifically in the extremities, are among the most commonly missed injuries. Previous studies have identified several factors that increase the risk of a missed injury, and those include head injuries, low Glasgow Coma Scale (GCS) scores, high ISS, and mechanically ventilated patients.[47] These factors are often present in multiply injured patients, and although the primary and secondary surveys performed in the emergency department are aimed at identifying life-threatening injuries, inadequate physical examinations, deviation from routine care algorithms, and misinterpretation/lack of adequate radiographs can all contribute to missed or delayed diagnoses. The tertiary survey, which includes a comprehensive physical examination and review of imaging studies within 24 hours after the primary survey, was implemented in the 1990s and resulted in the detection of more than 50% of previously missed injuries. If possible, the tertiary survey should be completed when the patient is conscious and responsive; however, this is not always plausible in severely injured patients within 24 hours of admission.

Drug and Alcohol Use

The incidence of drug and alcohol use in patients with MSK injuries has been reported to be as high as 50%. Prescription opiate use and abuse have also become more common in recent years and is a well-documented societal problem. Orthopedic trauma patients have a higher preinjury use of opioids than the general population. In addition, one study reported that lower-income and unemployed patients are more likely to feel that their surgeon is not prescribing them enough pain medicine, use their prescribed opioid medications at higher-than-recommended doses, and use additional opioid medications in addition to those prescribed to them. Several institutions have begun to implement multimodal pain management algorithms with good success in decreasing overall opioid administration and usage in orthopedic patients. Rates of alcohol abuse disorders in hospitalized trauma patient populations have been reported to be greater than 50% in some studies. Alcohol withdrawal syndrome occurs approximately 6 to 48 hours after the cessation of alcohol consumption and may be characterized by tremor, anxiety, agitation, seizures, and delirium tremens. As such, due to the increased prevalence of alcohol abuse in trauma patients, it is important to establish alcohol withdrawal protocols, screen for histories of abuse, monitor for symptoms, and consult appropriate services such as addiction management to provide resources to the patient.

Thromboembolic Complications

Multiply injured trauma patients are at significantly higher risk of developing deep venous thrombosis (DVT) and pulmonary embolism (PE), with reported rates as high as 60% in some studies. A systematic review reported the overall incidence of venous thromboembolism to be 12% in patients who received no prophylaxis and 7% in those who received mechanical prophylaxis.[48] Higher rates are likely seen in patients with multiple severe injuries (e.g., traumatic brain and spinal injuries) and those undergoing multiple surgeries. As such, the use of thromboprophylaxis is strongly recommended in hospitalized trauma patients because even with appropriate prophylaxis, venous thromboembolism remains among the leading causes of mortality in this patient population.

Recent systematic reviews have demonstrated that both pharmacologic and mechanical prophylaxis reduces the risk of DVT in trauma patients. The decision to begin pharmacologic prophylaxis in particular should be balanced with the potential risk of bleeding related to the patient's injuries, specifically in the setting of solid organ injury, intracranial hemorrhage, and spinal injury. The American Society of Hematology (ASH) 2019 guidelines for prevention of venous thromboembolism in hospitalized surgical patients recommended pharmacologic prophylaxis over no prophylaxis for patients undergoing major surgery in general. In a more recent randomized controlled trial comparing aspirin and low-molecular-weight heparin for thromboprophylaxis after fracture, the authors reported that in patients with extremity fractures who had been treated operatively or with any pelvic or acetabular fracture, thromboprophylaxis with aspirin was noninferior to low-molecular-weight heparin in preventing death and was associated with low incidences of DVT and PE and low 90-day mortality.[49] In a study of 12,211 patients, thromboprophylaxis was administered while inpatient and then for 21 days after discharge, with reported rates of DVT and PE in both groups to be $\leq$2.51%. Despite these updated findings, there remains a lack of a universally accepted protocol for orthopedic trauma patients, with a wide range of protocols used across the United States. Recent reviews of general dosing guidelines, combination therapy, timing/duration of anticoagulation, and numerous societal recommendations have been published for reference. An example protocol used at the author's institution is displayed in Table 40.7.

TABLE 40.7 Inpatient and Discharge Thromboembolism Prophylaxis Protocol

Isolated Upper Extremity Injury

- Preoperative: SCDs
- Postoperative: SCDs, EC ASA 81 mg PO BID
- Discharge: indication discussed with attending surgeon

Unilateral Lower Extremity Injury

- Preoperative/postoperative: SCDs, Lovenox 40 mg QHS
- Discharge: EC ASA 81 mg PO BID × 14 days to take with food

Hip/Pelvis/Acetabulum Fracture

- Preoperative/postoperative/nonoperative: SCDs, Lovenox 40 mg QHS
- Discharge: Eliquis 2.5 mg PO BID × 4 weeks

Bilateral Lower/Multiple Extremity Injuries

- Preoperative/postoperative: SCDs, Lovenox 40 mg QHS
- Discharge: Eliquis 2.5 mg PO BID × 4 weeks

Other

- Newly wheelchair-bound patients should be discharged on 4 weeks of Eliquis 2.5 mg PO BID.
- Baseline wheelchair-bound patients should be assessed case by case with the attending surgeon.
- Patients who are being discharged to return for staged orthopedic surgery should be discharged Lovenox 40 mg QHS until return to hospital.
- Patients that are at high risk for DVT (e.g., history of DVT/PE, hypercoagulable state, active cancer) require screening ultrasound to evaluate for DVT. Discharge on Eliquis for negative study, and discuss treatment with attending surgeon if positive study.

BID, Twice daily; *EC ASA,* enteric-coated aspirin; *DVT,* deep venous thrombosis; *PE,* pulmonary embolism; *PO,* by mouth; *QHS,* nightly; *SCD,* sequential compression device.

Fat Embolism Syndrome and Acute Respiratory Distress Syndrome

Multiply injured patients are at increased risk of cardiopulmonary complications, such as FES and ARDS secondary to an already diminished respiratory reserve. FES is a known complication of long bone fractures, with a reported incidence between 2% and 5% in patients with isolated long bone fractures and as high as 19% in multiply injured patients. FES is a clinical phenomenon characterized by systemic dissemination of fat emboli within the circulation, which can deposit in and disrupt the microvasculature. It is most common in orthopedic trauma patients and may present with skin (petechiae), central nervous system (altered mental status), respiratory (hypoxemia), and eye (retinal hemorrhages) manifestations. Multiple diagnostic criteria have been proposed, and the signs and symptoms may present within hours to days after injury or surgery. The treatment of FES generally involves respiratory support and elevation to a higher level of care.

Fixation of multiple lower extremity long bone fractures with intramedullary fixation poses a significant cardiopulmonary risk to polytraumatized patients. As the femoral or tibial medullary canal is instrumented with guidewires, reamers, and intramedullary nail implants, the marrow contents and intramedullary fat are released into circulation, causing activation of the coagulation cascade, platelet dysfunction, release of vasoactive substances and inflammatory cytokines, and subsequent neutrophil infiltration. In at-risk patients, this may result in the onset of FES, pneumonia, ARDS, multiple organ failure, and in some cases death. The increased risk of these complications after intramedullary fixation of long bone fractures has been well described, and in the setting of multiple long bone fractures, surgeons commonly opt for a staged fixation approach. However, there is a paucity of high-level data regarding actual cardiorespiratory burden with simultaneous versus staged fixation of multiple lower extremity injuries, and because of that no universal treatment guidelines exist. A recent study investigated the rate of cardiopulmonary complications in 146 patients with multiple lower extremity long bone fractures treated simultaneously or staged and found no difference in cardiopulmonary complications, which is in contrast to previous studies.[50]

ARDS is an acute respiratory failure and life-threatening condition characterized by the 2012 Berlin criteria (i.e., three strata of progressive hypoxemia, noncardiogenic cause, bilateral pulmonary infiltrates). Risk factors are many and include trauma, sepsis, crystalloid resuscitation, drug overdose, and FES. Early fixation (<24 hours) of fractures has been shown to reduce the incidence of FES and ARDS in trauma patients; however, there has been some debate about whether the method of fixation affects the incidence of FES. Additionally, separate clinical and experimental studies have suggested that the presence of chest injury, not the method of fracture fixation, is responsible for ARDS. Therefore, it is recommended that a multidisciplinary approach be taken to balance the perceived risks of surgery when deciding both treatment timing and method of fixation. In patients with severe acute chest injury and concomitant long bone fractures, it may be advisable to delay definitive fixation of the fracture with intramedullary devices until the patient's pulmonary status has stabilized. Temporary stabilization with external fixation may be warranted, which not only helps with resuscitation and pain control but also decreases the embolization of fat seen with moving fracture ends.

POSTOPERATIVE MOBILIZATION

The benefits of early fixation and mobilization of multiply injured patients have been discussed. However, a distinction between mobilization and weight-bearing is essential. Mobilization is transfer of the patient from the supine position, either under the patient's own power or with the help of nurses or therapists. This includes turning the patient every few hours by nursing staff, sitting the patient up in bed, or transferring the patient to a chair. All patients should be mobilized by the first or second postoperative day if their general condition permits; this can help prevent the development of postoperative complications.

Weight-bearing, in contrast, is transmission of a load through an extremity. In general, the goal of fracture care is to achieve an anatomic reduction with stable fixation that will restore function and allow the patient to begin motion as soon as possible. In some cases, often related to fracture site comminution or soft tissue injuries, the surgeon may choose to limit weight-bearing status to touch-down weight-bearing, partial weight-bearing, or non–weight-bearing completely. This recommendation is made while taking a variety of different patient and injury factors into consideration and also to protect the fixation construct and prevent early implant failure. It is also important to assess the patient's social, psychological, and overall mental status first to determine if a patient will be able to abide by weight-bearing restrictions. In polytraumatized patients, surgical fixation of certain injuries may be indicated in order to allow for the patient to mobilize sooner. An example of this might be treating a clavicle or humeral shaft fracture with open reduction and internal fixation so that the patient may use their upper extremities to mobilize with use of a walker. If patients are made non–weight-bearing after surgical fixation of an injury or are intubated and sedated in the intensive care unit, surgeons will still strongly recommend passive range of motion of involved joints to increase mobility and prevent stiffness. Early joint range of motion has been shown to be beneficial for joint health, as it promotes nutrition of the articular cartilage through movement of synovial fluid and has become a basic tenet of fracture care to decrease the morbidity associated with MSK injuries.

SUMMARY

In the setting of the multiply injured patient, preservation of a patient's life takes precedence over preservation of a limb. However, injuries to the axial and appendicular skeleton may be life-threatening in rare circumstances (e.g., hemorrhage or vascular injury from pelvic or long bone fractures) and must be promptly recognized and managed appropriately. MSK injuries represent a major cause of posttraumatic morbidity, as demonstrated by increased healthcare costs, lost workdays, physical disability, emotional distress, and diminished quality of life. Accordingly, it is essential that a thorough, comprehensive MSK examination be performed on every trauma patient upon presentation to identify life- or limb-threatening injuries and decrease the risk of missed or delayed diagnoses. This includes ordering and review of all appropriate imaging studies, laboratory tests, and placement of an orthopedic surgery consultation in timely fashion. Ideally, patients should not be transported from the trauma room, unless for emergent lifesaving interventions, until the orthopedic team has evaluated the patient, appropriately stabilized all injured extremities, and provided recommendations on any potentially emergent conditions. Most importantly, providing appropriate treatment of MSK injuries is truly a multidisciplinary endeavor. Only through collegial and efficient collaboration between all treating services—general surgery, vascular surgery, neurosurgery, spine surgery, plastic surgery, internal medicine, and physical therapy—are we able to ensure the best possible outcome for our patients.

de Ridder VA, Whiting PS, Balogh ZJ, Mir HR, Schultz BJ, Routt MC. Pelvic ring injuries: recent advances in diagnosis and treatment. *OTA Int*. 2023;6(suppl 3):e261.

Pelvic ring injuries are common after high-energy injury mechanisms and are associated with higher mortality secondary to acute life-threatening hemorrhage leading to shock and metabolic derangements. Implementation of organized institutional protocols for the acute management of these injuries has been shown to decrease mortality and improve outcomes. Early management should be focused on hemorrhage control and resuscitative measures.

Garner MR, Sethuraman SA, Schade MA, Boateng H. Antibiotic prophylaxis in open fractures: evidence, evolving issues, and recommendations. *J Am Acad Orthop Surg*. 2020;28(8):309-315.

Open fractures are commonly associated with high-energy trauma and have an increased risk of infection secondary to soft tissue damage and contamination. Early administration of appropriate antibiotic prophylaxis is one of the most important treatment interventions that can be initially performed and has been shown to drastically reduce the risk of infection and improve outcomes.

Major Extremity Trauma Research Consortium (METRC), O'Toole RV, Stein DM, et al. Aspirin or low-molecular-weight heparin for thromboprophylaxis after a fracture. *N Engl J Med*. 2023;388(3):203-213.

Venous thromboembolism (VTE) is a potentially fatal complication after orthopedic trauma. Prophylaxis (chemical or mechanical) reduces the risk of deep vein thrombosis (DVT) by around 50%. Previous guidelines recommend use of low-molecular-weight heparin (LMWH) in cases of orthopedic trauma patients. In this study, aspirin was demonstrated to be noninferior to LMWH in preventing all-cause mortality after orthopedic trauma, and there were similar rates of pulmonary embolism and deep venous thrombosis.

As firearm-related violence and injuries begin to rise in the United States, there continues to be minimal high-level evidence to guide treatment in patients with these injuries. Assessment of commonly associated injuries, such as neurologic and vascular, is an important part of their initial evaluation. These injuries present unique challenges in treatment and are associated with high rates of complications and morbidity.

Vallier HA, Moore TA, Como JJ, et al. Teamwork in trauma: system adjustment to a protocol for the management of multiply injured patients. *J Orthop Trauma*. 2015;29(11):e446-e450.

Early resuscitation of multiply injured patients requires a comprehensive and multidisciplinary team approach. As the trend continues to move more toward early appropriate care in these patients, it is important to develop institutional protocols to determine the adequacy of resuscitation when determining timing of definitive fixation.

TRAUMATIC BRAIN INJURY

Introduction

The goal of this section on traumatic brain injury (TBI) is not to give a comprehensive review of TBI epidemiology, basic science research, and clinical trials, but rather to provide surgeons with a practical approach to the initial management of traumatic injuries of the brain. At most US hospitals, trauma surgeons are the primary providers responsible for hospitalized TBI patients. General surgery residency has historically involved extensive exposure to the initial evaluation, stabilization, and intensive care management of trauma patients, a sizable percentage of whom are hospitalized with and affected by TBI.

Evidence-based guidelines form the basis of many institutional protocols for physicians caring for brain-injured patients. The following section on the management of TBI is based in large part on these guidelines. As with all practice guidelines, they can and need to be modified as dictated by the experience of the treating physician and in accordance with the needs of the patient and practice setting. The protocols laid out in the Advanced Trauma Life Support (ATLS) guidelines as well as the Best Practice Guidelines in the Management of TBI, both published by the American College of Surgeons (ACS), are invaluable practical resources,[1] as is the Brain Trauma Foundation Guidelines for the Management of TBI.[2] Nevertheless, data from high-quality clinical trials on the acute management of TBI are sparse, and thus, the following represents the best available evidence, including expert consensus in some cases.

Epidemiology

Worldwide, 69 million people experience a TBI annually, with higher incidences and fatality rates in low- and middle-income countries than in high-income countries. The majority of TBIs are mild, including concussions, but it is difficult to differentiate mild TBI from moderate or severe TBI in the prehospital setting.[3] Severe TBI is a leading cause of morbidity and mortality in the United States, and there are about 3 million TBI-related emergency department (ED) visits, hospitalizations, and deaths annually. More than 5 million people are known to be living in the United States with the unmeasured long-term functional, cognitive, and psychological effects of TBI, with annual direct and indirect costs approaching $80 billion. The 2022 National Academies of Sciences, Engineering, and Medicine report on TBI highlighted the long-term consequences of TBI on individuals, families, communities, and society at large.[4] Even after a "mild" TBI, more than 50% of patients report persistent symptoms and functional impairment a year after injury.

Classically, the epidemiology of TBI has been described using patient characteristics (e.g., age, sex), injury characteristics (blunt vs. penetrating), and injury severity (mild, moderate, and severe). TBI may occur in isolation or, perhaps 50% of the time, in combination with other traumatic injuries (i.e., in the polytrauma patient). The most common mechanisms of injury leading to TBI are motor vehicle collisions (MVCs) and falls, with MVCs predominating in low- and middle-income countries. Penetrating TBI constitutes a fraction of cases and ranges from mild to moderate to catastrophic depending on the trajectory of the primary ballistic injury. TBI and criminal offenses are bidirectionally linked, with a high prevalence of self-reported history of TBI in the incarcerated population. TBI overlaps with intimate partner violence and has disproportionately worse outcomes than do other forms of intimate partner violence.

TBI injury severity is described using the Glasgow Coma Scale (GCS), with subscores for eye opening, verbal response, and motor response summing to a range of 3 to 15 points. Mild TBI corresponds to GCS 13 to 15, moderate TBI to GCS 9 to 12, and severe TBI to GCS 3 to 8. The term *traumatic brain injury* actually encompasses a heterogenous group of diseases with distinct means of primary prevention, targets for treatment, and trajectories of recovery. There is also a growing awareness of the need to better classify TBI beyond mild, moderate, and severe, incorporating neuroimaging details, TBI-specific biomarkers (e.g., GFAP and UCH-L1), and disease modifiers including social determinants of health.

Pathophysiology

A TBI occurs when a direct or indirect force to the brain disrupts normal brain function. This force may be blunt or penetrating. The primary brain injury describes the injury at the time of impact and includes (1) fractures, (2) intracranial hemorrhage, and (3) diffuse axonal injury (DAI), which can each occur in isolation or in any combination. Secondary brain injury describes subsequent injury to the brain tissue caused by cerebral hypoperfusion and ischemia, hypoxia, increased intracranial pressure (ICP), metabolic dysregulation, and temperature instability, among other factors.

Primary Brain Injury: Fractures

Fractures of the skull, including the cranial vault and the skull base, occur when a direct blunt or penetrating force is applied to the bone at the moment of impact. Fractures can be classified as open versus closed (based on violation of the overlying skin and soft tissue), depressed versus nondepressed, and linear versus comminuted (Fig. 41.1A). Skull base fractures should always prompt an assessment for associated cranial nerve injuries, cerebrovascular injuries, and even cerebrospinal fluid (CSF) fistulas because of the close anatomic relationships. Although skull fractures can occur in isolation, they often occur together with intracranial hemorrhage. This is because disruption of the bony structure is frequently associated with disruption of the underlying meningeal arteries and/or dural venous sinuses.

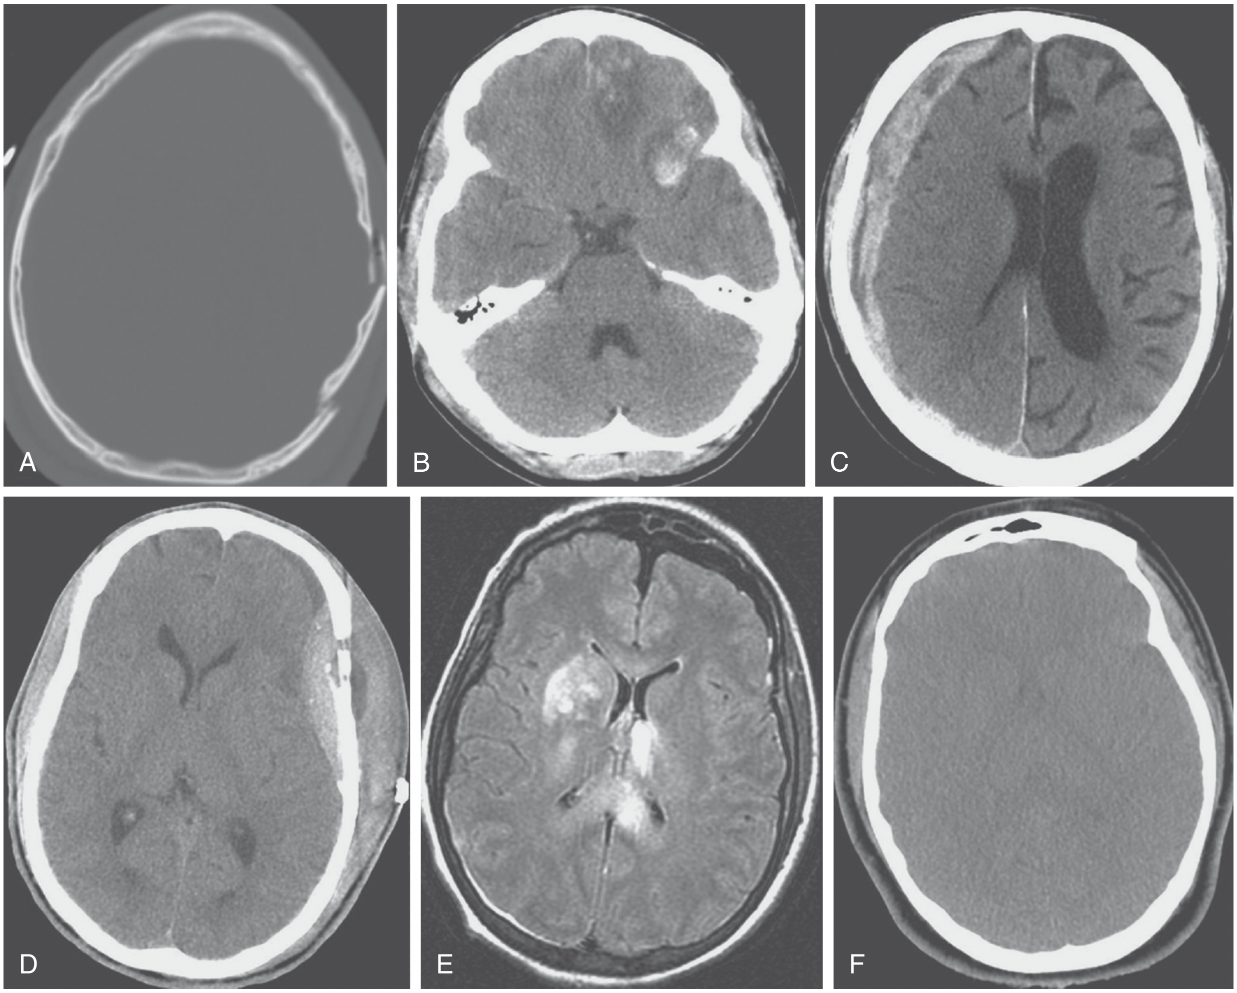

FIGURE 41.1 Typical radiographic findings in traumatic brain injury. All images are computed tomography (CT) except for (E), which is magnetic resonance imaging (MRI). (A) Comminuted, depressed skull fracture. (B) Intraparenchymal frontal lobe contusions. (C) Subdural hematoma with midline shift caused by mass effect. (D) Epidural hematoma with associated skull fracture and midline shift caused by mass effect. (E) Diffuse axonal injury on MRI. (F) Intracranial hypertension with effacement of the sulci and gray-white matter differentiation.

Primary Brain Injury: Intracranial Hemorrhage

Any bleeding within the skull is termed *intracranial hemorrhage*. Bleeding can occur in the spaces between the dura and skull (*epidural hemorrhage*, typically caused by a meningeal artery tear), between the dura and the arachnoid (*subdural hemorrhage*, caused by injury to the bridging veins between the brain and the dural venous sinuses), into the spinal fluid spaces surrounding the blood vessels feeding the cerebral cortex *(subarachnoid hemorrhage),* or into the brain parenchyma itself (*intraparenchymal or intracerebral hemorrhage,* sometimes caused by a "coup-contrecoup" mechanism). Small intraparenchymal bleeds may also be referred to as *contusions* or *bruises* to the brain parenchyma (see Fig. 41.1B). Although initially underwhelming on imaging and physical examination, these contusions can blossom and become life threatening within hours to days, earning them the label "talk and die." Blood within the cerebral ventricular system *(intraventricular hemorrhage)* may also be seen, although rarely in isolation because the blood must originate from somewhere.

Epidural and subdural hemorrhages occupy the space outside of the brain and are thus mostly likely to (1) place external pressure on the brain and put patients at risk for herniation and (2) be amenable to urgent surgical decompression, as described in the later sections on operative management of TBI. Fig. 41.1C–D highlight the different radiographic appearances of epidural and subdural hematomas as well as the associated mass effect caused by the Monro-Kelli doctrine. This doctrine states that any increase in intracranial blood (i.e., caused by ongoing hemorrhage) leads to a displacement of the brain and CSF within the fixed space of the skull. This process ultimately results in herniation as the building pressure caused by bleeding seeks an exodus by pushing the brain downward through the skull's foramen magnum or across rigid membranes like the tentorium or falx.

Subarachnoid hemorrhages are most commonly the result of trauma, but they may also occur after rupture of an intracranial aneurysm. The etiology of a subarachnoid hemorrhage is usually discernable from the patient history and distribution of bleeding on computed tomography (CT) imaging. This distinction is important to make soon after patient arrival, as aneurysmal bleeds are managed differently from TBI, but both carry risk of cerebral vasospasm.

Primary Brain Injury: Diffuse Axonal Injury

DAI, also referred to as *traumatic axonal injury* or *shear injury,* represents a radiographically insidious form of TBI that is often not seen on initial CT imaging. DAI is thought to be caused by rotational acceleration-deceleration injury to the white matter tracts of the brain, resulting in primary axotomy or functional or anatomic disruption of these pathways. In severe cases, this primary axotomy is then followed by a secondary axotomy of apoptosis and degeneration over the subsequent 6 to 12 hours.

DAI is usually diagnosed on magnetic resonance imaging (MRI) as multifocal hyperintense lesions at the gray-white matter interfaces, often graded in increasing severity with involvement of the cerebral lobes, corpus callosum, and brainstem (see Fig. 41.1E). However, visible lesions on both MRI and CT are believed to be just the tip of the iceberg of the actual primary injury. As such, it is virtually impossible to understand the true incidence and prevalence of DAI with current clinical neuroimaging.

DAI can occur with or without focal or structural TBI (i.e., intracranial hemorrhage and fractures). DAI ranges from mild TBI, akin to a concussion, to severe TBI. Mild cases of DAI may present with axonal stretching and transient neuronal dysfunction rather than complete disruption. DAI should be on the differential diagnosis of patients who fail to improve after surgical evacuation of a subdural or epidural hematoma, or in patients who remain unconscious despite the absence of intracranial hemorrhage on CT imaging, but the utility of pursuing current clinical MRI diagnostics is uncertain given its weak correlation with outcomes.

Secondary Brain Injury

Secondary brain injury refers to a cascade of events that results in additional, cumulative injury to the brain after the initial direct injury. At least half of all patients with hospitalized TBI have polytrauma or other associated traumatic injuries, which may place them at particular risk of secondary brain injury, while other competing life-threatening injuries require management. Cerebral hypoxia, or decreased oxygen delivery to the brain, is thought to be a key driver of secondary brain injury. Severe TBI can disrupt the normal physiology of cerebral blood vessel autoregulation. Adding systemic hypotension to this impaired autoregulation results in decreased cerebral blood flow and thus relative cerebral ischemia. This vicious cycle then is further exacerbated by systemic hypoxia, intracranial hypertension, and cerebral inflammation, leading to a cascade of excitotoxicity, calcium influx, and Na+/K+-ATPase dysfunction, ultimately culminating in neuronal cell dysfunction and neuronal cell death.

Elevated ICP, also known as *intracranial hypertension* (see Fig. 41.1F), is a global measure that may reflect multiple mechanisms at play in secondary brain injury, including edema (cellular or extracellular), cerebral venous outflow obstruction, hyperemia (engorgement of cerebral vessels caused by a loss of autoregulation and vasodilation), mass effect (expanding hematoma), and disturbances in CSF circulation. However, secondary brain injury may occur even in the absence of intracranial hypertension.

Preventing secondary brain injury is thought to be the cornerstone of potentially reversing the morbidity and mortality of TBI. At present, the management of secondary brain injury is limited to efforts to simply avoid hypotension and hypoxia while taking measures to control ICP and to maintain cerebral perfusion pressure (CPP). Multiple preclinical neuroprotective therapies are in the pipeline to prevent secondary brain injury in a more proactive fashion in the future, including glibenclamide and xenon gas.[5]

In some cases, primary and secondary brain injury also lead to persistent and irreversible neurologic deficits, with loss of neurologic function, cognitive decline, psychological alterations, and chronic disability. At least 3% of dementia cases in the general population are attributable to TBI, although this is likely an underestimate.[3]

Prehospital and Emergency Department Management

Severe TBI may cause death within the first few hours after injury as a result of airway compromise or herniation. Secondary brain injury also begins soon after injury in the prehospital setting. As such, prompt and focused prehospital care is essential to avoid hypoxia, preserve cerebral blood flow, and identify candidates for surgical decompression. Treatment begins on scene by prehospital professionals and continues until handoff in the emergency room. At present, prehospital identification of patients with possible TBI relies on physical examination, including evidence of obvious injury to the head or neck and determination of the GCS, described later, in combination with the severity of the known mechanism of injury.

Patients with suspected moderate to severe TBI (GCS ≤13) should be transported directly from the scene to the highest-level trauma center available in a defined trauma system for prompt CT neuroimaging and neurosurgical care.[1] In most cases, any patient with a suspected TBI of any type, particularly in combination with polytrauma, should be transported directly to the nearest trauma center rather than stabilized at a nontrauma center first. Transfer of patients from one hospital to a higher level of care should follow ATLS guidelines, and the transferring center should ensure a secure airway, adequate ventilation, and circulation before transfer. Vigilance and attention to detail as well as communication between the transferring and accepting teams are key to the successful management of these patients.

Avoidance of Hypoxia, Hypotension, and Hyperventilation

It is critical that emergency medical services (EMS) and other prehospital professionals anticipate, prevent, and avoid hypoxia (<90% saturation), hypotension (<100 mm Hg systolic blood pressure [SBP]), and hyperventilation (end-tidal CO_2 [$ETCO_2$] less than 35) in any patient with suspected TBI, with frequent prehospital monitoring (at least every 5 minutes, or continuously where available).[2] For example, the Excellence in Prehospital Injury Care Study implemented prevention against these three prehospital pitfalls, thus improving TBI outcomes across more than 130 EMS systems and agencies throughout the state of Arizona.[6] Ventilation of patients with altered levels of consciousness should aim for an $ETCO_2$ of 35 to 45 mm Hg. Hypothermia and hyperthermia should also be avoided.

Airway, Breathing, and Circulation

As with all trauma patients, airway, breathing, and circulation (ABC) should be the initial focus of prehospital care. Attention should be first directed to securing a patent airway, establishing adequate ventilation and oxygenation, and maintaining adequate circulation—key steps to avoid hypotension and hypoxia and thereby minimize secondary brain injury. Because of this critical need to avoid hypoxia, all patients with suspected TBI should be placed on oxygen via nasal cannula or face mask and monitored for hypoxemia (oxygen saturation <90%), which should be corrected promptly. In patients with suspected severe TBI and/or the inability to maintain an adequate airway, or if hypoxemia is not promptly corrected by supplemental oxygen and bag-valve-mask ventilation in conjunction with an oropharyngeal airway, a definitive advanced airway (e.g., endotracheal tube) should be established by a trained prehospital professional.

With regard to circulation in the prehospital setting, hypotensive patients with suspected TBI should be treated with isotonic fluids and/or blood products if available in an effort to treat and/or limit hypotension to the shortest duration possible. There is weak evidence for the use of hypertonic fluids in the prehospital setting. Table 41.1 shows the goals of treatment in the prehospital setting and beyond, as defined by the Brain Trauma Foundation and ACS Trauma Quality Improvement Program (TQIP) Best Practice Guidelines for TBI.

Neurologic Assessment With the Glasgow Coma Scale

Originally developed in 1974, the GCS is the most widely used scale to quickly assess the level of consciousness after a possible TBI. The GCS includes assessment of eye opening (up to 4 points), motor response (up to 5 points), and verbal response (up to 6 points), for a total of 3 to 15 points (Table 41.2). The GCS is a repetitive, reproducible scale that allows for ongoing neurologic assessments performed by a variety of healthcare professionals both in the prehospital and hospital environment. Of the three components, the motor score carries the most prognostic weight. Although assessment of the GCS is critical to the initial management of a patient with suspected TBI, it should only be done after stabilization of the ABC in a trauma patient. Provided that patient stability allows, the GCS should be measured before sedative or paralytic medications are administered.

TABLE 41.1 Goals of Treatment for Traumatic Brain Injury

PARAMETER	PREHOSPITAL AND ED[a]	INTENSIVE CARE UNIT[b]
Oxygenation (pulse oximetry)	≥90%	≥94%
Oxygenation (PaO_2)		80–100 mm Hg
Circulation (systolic blood pressure)	100–150 mm Hg	≥100 mm Hg
Ventilation (breaths per minute)	10	35–45 mm Hg
Ventilation ($ETCO_2$)	35–40 mm Hg[c]	7.35–7.45
Ventilation ($PaCO_2$)		
Acid-base status (pH)		
Intracranial pressure (ICP)		<22 mm Hg
Cerebral oxygenation ($PbtO_2$)		≥15 mm Hg
Cerebral perfusion pressure (CPP)		60–70 mm Hg[d]
Temperature	36.0°C–37.0°C	36.0°C–37.9°C
Glucose		100–180 mg/dL
Serum sodium		135–145 mEq/L[e]
Serum osmolality		300–320 mOsm
Hematologic (INR)		≤1.4
Hematologic (platelets)		$\geq 75 \times 10^3/mm^3$
Hematologic (hemoglobin)		≥7 g/dL

[a] Based on Brain Trauma Foundation guidelines.

[b] Based on American College of Surgeons Trauma Quality Improvement Program Best Practice Guidelines for Traumatic Brain Injury.

[c] Except in cases of imminent herniation, for which a goal of 30 to 35 mm Hg is acceptable.

[d] Depending on status of cerebral autoregulation.

[e] Except when patients are undergoing tier 2 hyperosmolar therapy for intracranial hypertension.

ED, Emergency department; *$ETCO_2$,* end-tidal carbon dioxide; *INR,* international normalized ratio; *$PaCO_2$,* partial pressure of carbon dioxide; *$PbtO_2$,* brain tissue oxygen tension; *PaO_2,* partial pressure of oxygen.

The GCS score should be determined at least every 30 minutes in the prehospital setting and whenever there is an apparent change in mental status to identify improvement or deterioration over time. Often, the prehospital GCS will vary from the GCS determined on arrival to the ED or the postresuscitation GCS. An initial depressed GCS may reflect true TBI severity, but it may also reflect hemorrhagic shock with poor perfusion to the brain or the impact of hypoglycemia, seizure activity, sedatives, or other ingestions. Once one or more of these reversible conditions are addressed, the GCS may improve. Alternatively, the GCS may decrease because of an interval worsening of the actual brain injury or physiologic state. Repeat assessments are critical to identify and treat underlying TBI and other reversible causes of morbidity and mortality in the trauma population. In addition to GCS, other neurologic assessment scales in some use in the prehospital settings include the Simplified Motor Score (SMS) and the Simplified Verbal Score (SVS).

TABLE 41.2 Neurologic Assessment Using the Glasgow Coma Scale (GCS)

EYE-OPENING RESPONSE		VERBAL RESPONSE		MOTOR RESPONSE	
EYE SCORE	**RESPONSE**	**VERBAL SCORE**	**RESPONSE**	**MOTOR SCORE**	**RESPONSE**
4	Spontaneous	5	Oriented	6	Obeys commands
3	To speech	4	Confused	5	Localizes to painful stimulus
2	To pain	3	Inappropriate responses	4	Withdraws to painful stimulus
1	No response	2	Incomprehensive responses	3	Flexion to painful stimulus
		1	No response	2	Extension to painful stimulus
				1	No response

Summed GCS scores range from 3 to 15, with GCS 3 to 8 corresponding to severe traumatic brain injury (TBI), 9 to 12 to moderate TBI, and 13 to 15 to mild TBI. Intubated patients receive a "T" in place of the verbal response, so the best possible score for an intubated patient is GCS 11T.

Pupil Examination

The prehospital evaluation of a patient with suspected TBI should also include a thorough assessment of pupil size, symmetry, and reactivity. The pupil examination allows an understanding of the function of many different neuroanatomic pathways and, as such, adds value to the acute management and long-term prognosis of TBI. When present in combination with a depressed GCS, abnormalities of pupillary response or asymmetry may portend impending neurologic deterioration or poor long-term neurologic outcomes. The pupil examination should be done at the same time as the GCS assessment, again once the patient has been stabilized from an ABC standpoint.

The bilateral pupillary examination consists of evaluation of pupil size, symmetry, and reactivity to light. The normal light reflex requires a functioning lens, retina, optic nerve, brainstem, and oculomotor nerve. The consensual pupil response to light assesses the function of the contralateral oculomotor nerve. Infrared pupillometry may allow for more consistent pupil assessment evaluation across a range of prehospital and hospital settings but has not yet been implemented widely. An abnormal pupillary examination can be an early warning sign in the setting of TBI. Absence or asymmetry of these reflexes may indicate herniation or brainstem ischemia. New pupillary changes or anisocoria (unequal pupils with >1 mm of difference) may indicate an increase in ICP that would require reimaging and/or intervention. For example, ongoing bleeding from an epidural or subdural hematoma may be causing impending transtentorial herniation, which may be reversible with emergent surgical evacuation. A unilateral fixed and dilated pupil may represent herniation, whereas bilateral fixed and dilated pupils may reflect global anoxia and dismal prognosis.

Pupillary abnormalities in a patient with a normal GCS should also be noted and communicated to the ED team upon handoff, but these are less associated with the diagnosis and severity of TBI. In the setting of traumatic globe rupture or other ophthalmologic trauma, the pupillary examination may be unreliable. Metabolic, pharmacologic, or toxic etiologies can also cause pupillary abnormalities, as can prior ophthalmologic procedures or genetic conditions. Nevertheless, pupillary abnormalities should be presumed to indicate a primary brain injury until proven otherwise.

Prehospital Management of Intracranial Pressure

As mentioned previously, hyperventilation should be avoided in patients with suspected TBI, and in those with advanced airway monitoring, ventilation should target an $ETCO_2$ of 35 to 45 mm Hg. The exception is in patients with a prehospital GCS <9 and signs of imminent herniation, including Cushing triad (hypertension, bradycardia, irregular breathing pattern), posturing or lateralizing findings, and unilateral or bilateral fixed, dilated pupils. In such cases, hyperventilation should temporarily target an $ETCO_2$ of 30 to 35 mm Hg. Hyperosmolar therapy (e.g., mannitol and hypertonic saline) should not be administered for the prophylactic treatment of suspected elevated ICP in the prehospital setting and has not shown benefit in large randomized clinical trials. At present, prehospital administration of tranexamic acid (TXA) is used empirically in some practice settings for clot stabilization in patients with suspected intracranial hemorrhage or elevated ICP.

Emergency Department Management

The ED management of patients with suspected TBI follows the same principles as in the prehospital setting. First, ABC should be addressed and stabilized. Next, a thorough neurologic assessment should be done, including evaluation of the GCS and pupils. Prompt neuroimaging is necessary to guide further management, including surgical decompression. While still in the ED, candidates should be identified by history for expeditious reversal of coagulopathy and/or impaired platelet function with the appropriate agents, typically prothrombin complex concentrate for anticoagulants and desmopressin for nonaspirin antiplatelet agents.

Neuroimaging

A noncontrast head CT scan is used to evaluate the presence or absence of fracture, intracranial hemorrhage, midline shift, and appearance of the basal and perimesencephalic cisterns (see Fig. 41.1). At the same time, routine scanning of the cervical spine should also be performed to rule out acute fractures or traumatic dislocations. If life-threatening injuries in the polytrauma patient mandate immediate operative exploration for hemorrhage control, CT scanning should be delayed until after patient stabilization. Should there be concern for undiagnosed intracranial injury and/or extended intraoperative time, intraoperatively placed ICP monitors can be a useful adjunct. In some clinical scenarios, if a polytrauma patient has an impaired GCS and a suspected unilateral intracranial mass lesion, as evidenced by a unilateral fixed and dilated pupil, an exploratory burr hole may be performed in the operating room concurrently with the laparotomy or thoracotomy. However, this situation should rarely occur, as CT neuroimaging is best used to guide emergent evacuation of epidural and subdural hematomas.

Operative Management

It is critical to promptly identify patients with TBI who would benefit from surgical evacuation. In general, the types of TBI most amenable to evacuation are intracranial hemorrhage outside the brain (i.e., epidural and subdural hemorrhages, termed *mass lesions*). An epidural hematoma more than 30 mL in size in association with neurologic deficits or radiographic signs of midline shift or effacement of the basal cisterns is commonly accepted as criteria for emergent craniotomy (see Fig. 41.1C–D). A subdural hematoma of at least 1 cm in size or with any midline shift in combination with a decline in neurologic examination should also prompt evacuation. Regardless of examination findings, a large mass lesion should be evacuated before neurologic deterioration develops, if in accordance with a patient's goals of care. Epidural and subdural hematomas are treated similarly with a formal craniotomy centered on the clot, rather than a burr hole. Depending on the degree of brain swelling and specific clinical scenario, the neurosurgeon may elect to leave the bone flap off (termed a *craniectomy*) to allow the brain to heal before coverage. A recent international clinical trial reached equipoise on the question of routine craniectomy versus craniotomy.[7]

ICP monitors are often placed at the time of craniotomy, particularly for patients with a preoperative GCS <8. The decision about whether to place an ICP monitor is at the operating surgeon's discretion and involves consideration of preoperative examination findings, the degree of swelling of the brain at the time of the operation, and potential risk for deterioration. Postcraniotomy patients are managed similarly to those with nonoperative TBI (see "Critical Care Management" and Table 41.1).

Decompressive craniectomy for intracranial hypertension in the absence of mass lesions is performed at some institutions as part of tier 3 management of elevated ICP, but this practice is not well supported by the literature.[8] The 2011 randomized controlled DECRA trial (Decompressive Craniectomy in Patients with Severe Traumatic Brain Injury) demonstrated that the successful reduction in ICP brought out by decompressive craniectomy was associated with worse neurologic outcomes at 6 months with similar findings in the 2016 RESCUEicp trial (Randomised Evaluation of Surgery with Craniectomy for Uncontrollable Elevation of Intracranial Pressure).

Critical Care Management

Goal-directed TBI treatment extends care from the prehospital and ED arenas to the intensive care unit (ICU) for patients with a confirmed diagnosis of moderate to severe TBI (see Table 41.1). As before, adequate oxygenation and normocapnia should be maintained. Systolic and mean arterial blood pressure should be tracked closely to avoid hypotension and to optimize CPP. Paroxysmal sympathetic hyperactivity can also occur in patients after severe TBI and is associated with elevated catecholamines resulting in hypertension and other negative effects.[10] Body temperature, glucose levels, and electrolytes should be maintained in the normal range. Hyponatremia should specifically be avoided because of the risk of cerebral edema. Coagulopathy should be reversed when apparent on laboratory testing or a history of taking anticoagulants to limit the expansion of intracranial bleeding.[9] Patients with severe TBI merit frequent monitoring of their serum sodium and osmolality levels, as they are at risk of developing diabetes insipidus or the syndrome of inappropriate antidiuretic hormone (SIADH).

Intracranial Pressure Monitoring and Management

ICP monitoring is indicated for comatose patients (GCS ≤8) with evidence of structural brain injury on CT imaging, or in patients judged to be at high risk for progression of their primary brain injury (e.g., because of large contusions or coagulopathy). ICP monitoring may also be considered in patients with moderate TBI undergoing urgent extracranial surgery. The placement of an ICP monitor allows for continuous or intermittent measurement of CPP, defined as the mean arterial pressure (MAP) minus the ICP [CPP = MAP – ICP]. The CPP should be maintained at 60 to 70 mm Hg to optimize cerebral blood flow and to minimize secondary brain injury. ICP should be kept below 20 to 25 mm Hg, but importantly, monitoring should not replace careful, repeated neurologic assessments and prompt repeat CT imaging in cases of neurologic deterioration.

ICP monitoring can be accomplished with either an external ventricular drain (EVD) or an intraparenchymal monitor. Either type can be placed in the operating room or ICU. The advantage of an EVD over an intraparenchymal bolt is the ability to drain CSF in order to lower ICP. Monitors placed in the subdural or epidural place are also available, but these tend to be less accurate and are thus less frequently used. When available, ICP monitoring in the appropriate patient population appears to be associated with a more intensive therapeutic approach and lower short-term mortality.[10] In underresourced settings, reasonably good outcomes from severe TBI can still be obtained using institutional protocols that include empiric treatment of elevated ICP, repeat imaging, and meticulous clinical examinations.

Treatment of elevated ICP or intracranial hypertension (persistent elevation above 22 mm Hg) follows the three-tiered approach recommended by the ACS TQIP guidelines.[1] Other groups, including the Seattle International Severe Traumatic Brain Injury Consensus Conference (SIBICC), recommend a slightly different three-tiered algorithm.[11] Serial CT scans are critical throughout this treatment algorithm, and their use should be tailored to the individual clinical scenario. Tier 1 involves elevating the head of the bed to 30 degrees while keeping the head in a neutral position to use gravity to improve cerebral venous outflow, taking care to ensure that cervical spine immobilization devices do not obstruct jugular venous flow. Tier 1 also involves the use of short-acting sedation agents (e.g., propofol, fentanyl) in intubated patients to allow for frequent neurologic reassessments off sedation. When available, intermittent drainage of CSF with an EVD or ventriculostomy also decreases ICP and is considered part of tier 1 management.

If the ICP remains persistently elevated above 22 mm Hg, tier 2 management includes the use of hyperosmolar therapy with either mannitol or hypertonic saline. Serum sodium and osmolality should be monitored every 6 hours while patients are receiving hyperosmolar therapy, and treatment should be held if levels reach 160 mEq/L or 320 mOsm/L, respectively. Cerebral autoregulation should be assessed by a trained intensivist as described in the recent SIBICC guidelines.[11] Neuromuscular paralysis should be employed with a single test dose, followed by continuous infusion if the test dose is successful in reducing ICP (the infusion is considered tier 3 treatment). Hyperventilation to a $PaCO_2$ of 30 to 35 mm Hg may be considered, although brain hypoxia may occur as a side effect because of reduced cerebral blood flow. At some centers, advanced neuromonitoring, including measurement of jugular venous oxygen saturation and brain tissue oxygenation, appears to help inform management of intracranial hypertension.[9] Multiple randomized controlled trials are currently underway to assess the added benefit of brain tissue oxygenation in the management of these patients, which remains an area of active debate.

Tier 3 management of intracranial hypertension includes consideration for decompressive bilateral craniectomy (with the reservations described earlier), continuous neuromuscular blockage (if the test dose in tier 2 was successful), or barbiturate coma with continuous electroencephalogram (EEG) monitoring for titration to burst suppression. Institutional protocols may guide selection of tier 3 approaches, and high-quality data are limited. Hypothermia is not recommended for salvage treatment for intracranial hypertension.[8] In a patient who is deeply sedated with or without paralysis, providers rely on the pupillary examination and ICP measurements to determine any change in intracranial dynamics. A persistently elevated ICP and/or a new blown pupil necessitates emergent CT neuroimaging.

Other Considerations for Critical Care Management

Patients with severe TBI are known to have increased energy or caloric requirements. As such, nutritional support is critical and should begin as soon as possible after injury, ideally within 24 to 48 hours, with full nutrition by 7 days after injury at the latest. Enteral nutrition is preferred. The hypermetabolic and hypercatabolic state of TBI lasts from 1 week to several months after the injury. Steroids have no benefit in the management of TBI and should not be used. Other therapies that should be avoided in the management of TBI are listed in Table 41.3.

Prophylactic use of anticonvulsant drugs should be given to prevent early posttraumatic seizures within the first week. Once there is no evidence of ongoing intracranial hemorrhage, pharmacologic prophylaxis for venous thromboembolism (VTE) should be started as soon as 24 to 48 hours after injury in TBI patients, because of the high rates of VTE in this population. Adrenergic blockage with β-blockers is commonly used in patients with severe TBI who are deemed at risk of paroxysmal sympathetic hyperactivity, or "storming," although evidence for benefit is variable. The dopamine agonist amantadine may improve cognitive function after TBI, especially when give within the first week of injury.[12] Early tracheostomy (within the first 5–7 days) should also be considered in patients with TBI requiring mechanical ventilation to reduce risk of ventilator-associated pneumonia and other complications. Other detailed considerations for the critical care management of patients with severe TBI are beyond the scope of this chapter and have been covered elsewhere.[13]

TABLE 41.3 Treatments Not Recommended in the Management of Severe Traumatic Brain Injury

Mannitol by non-bolus continuous infusion
Scheduled infusion of hyperosmolar therapy (e.g., every 4–6 hours)
Lumbar drainage of cerebrospinal fluid
Furosemide
Routine use of steroids
Routine use of therapeutic hypothermia to temperatures <35°C
High-dose propofol to attempt EEG burst suppression
Hyperventilation to decrease $PaCO_2$, <30 mm Hg
Routinely raising CPP >90 mm Hg
Platelet transfusions in adults on antiplatelet therapy
Antibiotic prophylaxis for external ventricular drain placement

CPP, Cerebral perfusion pressure; *EEG,* electroencephalogram; *$PaCO_2$,* partial pressure of carbon dioxide.

Prognostication and Long-Term Outcomes

This chapter focuses on the acute management of TBI and will not delve into the chronic phase of recovery and rehabilitation, which often extends for years even after a mild TBI with intracranial hemorrhage. After discharge, TBI recovery is varied and poorly understood, with predictions limited to 6 months. It is unknown at what point TBI recovery plateaus and remains fixed. In some patients, post-TBI neuroplasticity continues for multiple years. The path of recovery after TBI encompasses at least four domains: biologic, psychological, sociologic, and ecologic (including economic).[4] Patients experiencing severe or recurrent TBI may be at higher risk for long-term neurodegenerative conditions, including the development of dementia.[3]

The most commonly used outcome metrics after TBI are mortality and the Glasgow Outcome Scale-Extended (GOSE), which measures disability and functional recovery (Table 41.4). However, GOSE has its limitations, and long-term patient-centered outcomes for TBI are needed.[14] While patients are in the acute phase of recovery, other scales may be used, such as the Rancho de Los Amigos Scale or the Galveston Orientation and Amnesia Test. These scales help assess a patient's short-term progress and are used to identify patients who would benefit from specific brain-related therapies after hospital discharge.

Currently available prognostic models do not adequately predict long-term outcomes for individual patients and should be used with caution when making treatment-limiting decisions. Despite the broad acceptance of TBI prognostic models such as IMPACT and CRASH-TBI in the research arena, they are infrequently used in clinical practice and predict only 35% of the variance in patient outcomes.[3] One exception is the Baylor score for penetrating intracranial gunshot wounds, which does adequately predict mortality and functional outcomes to inform goals-of-care discussions in the acute setting.[15] However, in general, clinical fluctuations during the first 72 hours after injury may help inform prognosis and trajectory, and patients with severe TBI should receive full treatment for *at least* 72 hours unless their goals of care do not align with this trial of full treatment. There is a growing consensus in the field that premature withdrawal of life-sustaining measures (i.e., <72 hours) can lead to a self-fulfilling prophecy of fatalism or inappropriate therapeutic nihilism.[16] A substantial minority of patients with seemingly devastating TBIs can recover to independent functional status.

TABLE 41.4 Glasgow Outcome Scale-Extended (GOSE) Score for Traumatic Brain Injury Outcomes

GOSE SCORE	NEUROLOGIC FUNCTIONAL PERFORMANCE
1	Dead
2	Vegetative state
3	Lower severe disability (completely dependent on others)
4	Upper severe disability (dependent on others for some activities)
5	Lower moderate disability (unable to return to work or participate in social activities)
6	Upper moderate disability (return to work and/or social functions at reduced capacity)
7	Lower good recovery (minor social or mental deficits)
8	Upper good recovery

Ultimately, “no head injury is too severe to despair of, nor too trivial to ignore” (Hippocrates, 400 BCE). Better prognostic modeling in the future may translate to better TBI care, guiding patient and family expectations, goals of care, and best treatment. Prognostic stratification would allow us to understand which TBI subgroups benefit most from therapies in the preclinical pipeline to inform clinical trials that could change practice for TBI care. Multiple TBI therapies have failed in clinical translation because of basic challenges in patient selection and predicting TBI recovery. Until active targeted neuroprotective treatments become available for TBI, providers should adhere to the ATLS principles of ABC, with minimization of secondary brain injury and then prompt neuroimaging to identify mass lesions appropriate for neurosurgical evacuation.

PERIPHERAL NERVE INJURIES

Upper and lower extremity peripheral nerve injuries are extremely common, resulting from traumatic or iatrogenic mechanisms including crush, stretch/traction, laceration, or a combination thereof. An estimated 3% of all patients presenting to a Level 1 trauma center have a peripheral nerve injury to the upper extremity.[17] From an iatrogenic standpoint, several surgical procedures have been associated with peripheral nerve injuries including shoulder (1%–8%), hip (0.17%–7.6%), and knee (0.3%–1.3%) arthroplasties.[18]

Types of Peripheral Nerve Injuries

The two major nerve injury classification systems are Seddon and Sutherland.[17–19] The Seddon classification divides nerve injuries broadly into neuropraxia, axonotmesis, and neurotmesis (Table 41.5). Neuropraxic injuries have intact axons, with a conduction block at the site of the lesion. The associated demyelination affects the speed of nerve transmission; however, the conduction block can be improved with elimination of the insulting agent (i.e., compression). With neuropraxic injuries, there is the potential for spontaneous recovery within 3 months.

Axonotmetic injuries are characterized by damage to the continuity of axons, which can occur with crush and compression/traction injuries. In this nerve injury, the basal lamina remains intact. Lastly, neurotmetic injuries are characterized by complete nerve transection, including the basal lamina; the nerve is markedly damaged and disorganized.[20,21] During axonotmesis and neurotmesis, Wallerian degeneration occurs distal to the site of injury. With axonotmesis and neurotmesis, nerve recovery is seldom possible without surgical intervention because there is loss of axonal continuity.[17,19]

TABLE 41.5 Seddon Classification of Nerve Injuries

Seddon and Sunderland Classification System of Peripheral Nerve Injury (Including Mackinnon and Dellon Modification)

SEDDON	SUNDERLAND	
Neuropraxia	Type 1	Focal demyelination. Axon remains intact.
Axonotmesis	Type 2	Axonal continuity lost. Endoneurium, perineurium, and epineurium remain intact.
	Type 3	Axonal continuity lost. Endoneurium disrupted. Perineurium and epineurium remain intact.
	Type 4	Axonal continuity lost. Endoneurium and perineurium disrupted. Epineurium remains intact.
Neurotmesis	Type 5	Complete disruption of nerve structures.
	Type 6	Mixed injury.

From Lin JS, Jain SA. Challenges in nerve repair and reconstruction. *Hand Clin.* 2023;39:403-415.

With increased clinical and basic science research, it became clear that the Seddon classification alone does not comprehensively capture the complexity and spectrum of nerve injuries. To address this, the Sutherland classification was created; this system further subdivides the Seddon classification based on the layers of the nerve that are damaged. Although the Sutherland classification is more specific, it is often difficult to determine the level of injury based on clinical examination alone. Neuropraxia is designated as a first-degree injury, and neurotmesis is a fifth-degree injury and includes damage to all structures within the nerve, including the epineurium. Axonotmesis includes second-, third-, and fourth-degree injuries with variable damage to the internal architecture of the nerve while maintaining the outer epineurium. A sixth-degree Sutherland injury refers to a mixed injury comprising conduction block and axonal loss/discontinuity.[21]

Clinical Evaluation of Patients With Nerve Injury

A careful history taking and physical examination are of paramount importance, with a focus on the mechanism and timing of the injury relative to presentation. Nerve injuries should be suspected among patients with hyperesthesia, sensory, or motor deficits attributable to a specific nerve or common procedure and/or laceration or wound directly in the path of a specific nerve. For upper extremity nerve injuries, the patient’s handedness and occupation are important aspects of the history. Open wounds should be carefully cleaned and inspected for injured structures. Sensation can be assessed using a two-point discriminator, Semmes-Weinstein monofilaments, or the subjective “tens” assessment (a patient compares sensation in the region of injury to the contralateral uninjured area with a numerical value out of 10).[19,22] When percussion over the area of nerve injury produces electric shocks, or “pins and needles,” or an otherwise painful stimulus in the distribution of the nerve, this is referred to as a *Tinel sign.* A Tinel sign is indicative of disrupted axons and can be used to make the diagnosis of a nerve injury as well as follow progression of nerve healing after repair.

Mechanism of the Injury

It is important to understand the time that has occurred between injury and presentation as well as associated structures that have been injured. The condition of the wound associated with a nerve injury is critical because it informs the type of operative wound management as well as the timing of definitive nerve repair. Wounds created by sharp injury (knife/scalpel) have minimal contamination and devitalized tissue; the area of tissue damage is easily defined and well delineated. Dirty wounds include open fractures or those resulting from gunshot injuries; these injuries are devastating with a large zone of injury. Penetrating, blast, crush, and stretch injuries can be associated with vascular, soft tissue, or bone injuries, which can affect the timing and outcome of nerve repair. Vascular and bony injuries should be repaired, and the extremity should be stabilized before nerve repair. In wounds with significant tissue damage, the wound or nerve injury may not be suitable for acute repair/reconstruction, and the zone of nerve injury may not be clearly delineated. For these reasons, it may not be appropriate to perform an immediate nerve repair, but instead, tag the nerve ends so that they can be easily identified later for a delayed repair.

Nerve Conduction/Electrodiagnostic Studies

Nerve conduction studies (NCSs) provide information on the health of the axons and whether there is demyelination or continuity. Localization of nerve injuries is possible by detecting focal slowing or a conduction block on NCS. After nerve transection, conduction may be detectable for up to 72 hours until Wallerian degeneration occurs (the nerve end distal to the injury will not elicit a response upon stimulation).[21] Electromyography (EMG) measures muscle response and innervation through the detection of motor unit potentials and muscle recruitment. Denervation is heralded by fibrillations and fasciculations but can take up to 14 days to become detectable; therefore, EMG should not be ordered before this. As such, 3 weeks after closed injury is an appropriate time to order the first EMG to distinguish neuropraxic from more neurotmesis-type injuries.[23] When voluntary motor units are seen on EMG, this is suggestive of muscle recovery and reinnervation.

Ultrasonography and Magnetic Resonance Neurography

High-resolution ultrasonography (USN) is useful in the acute setting to detect nerve injury, including continuity as well as derangements in the fascicular topography. USN has several advantages, including decreased cost, dynamic evaluation, and minimal discomfort, and can be performed in the presence of implanted devices or hardware.[24] Sonographic grading of nerve injuries can be made based on the relative echogenicity of the nerve components including the epineurium, perineurium, axons, and fascicles; however, USN is not able to adequately visualize the endoneurium, and the quality of the images is dependent on the expertise of the operator.[24] Nerves that are entrapped or tethered in scar can be detected based on the appearance of an indentation and dilation proximal or distal to the affected area. A neuroma-in-continuity can be detected based on the presence of a nerve with maintained epineurium but with focal dilatation and effaced internal architecture.[24] On USN, completely transected nerves demonstrate epineurium with an intervening gap and possibly a proximal stump neuroma depending on the time after injury.[24]

Magnetic resonance neurography (MRN) is a powerful tool to detect and define the extent of peripheral nerve injuries. MRN relies on the specific properties of water in nerves and provides enhanced images, allowing for the detection of a nerve lesion. This information is incredibly helpful and accelerates surgical decision-making when the site or extent of the injury is not otherwise clear on physical examination or EMG.[17] MRN has increased spatial resolution and anatomic detail compared with USN but can be limited by the presence of hardware, although newer MRN protocols are available to accommodate the presence of metal.[18] MRN is also preferable to USN when the nerve of interest is deep, for example, in the axillary or lumbosacral space.[18] In addition to visualizing the nerve, MRN can detect muscle denervation and affords a global assessment and comparison of muscles in the area to detect changes.[18]

Timing of Repair

After a sharp laceration, if a patient presents with a nerve deficit in the zone of injury or distally, surgical exploration within the week is recommended to maximize the opportunity for primary repair; if later exploration is necessary, a discussion of nerve reconstruction with the patient is needed. Early primary repair is associated with improved outcomes. Blunt penetrating injuries in the absence of an associated vascular injury are often observed for spontaneous recovery. A baseline EMG at the time of injury is recommended. After 3 months of observation, if no recovery is noted, EMG is recommended to assess the extent of nerve injury, with a decision to proceed with surgical exploration or continued observation made based on the EMG results. Crush and compression injuries result in increased intraneural pressures and nerve dysfunction. These injuries should be observed for 3 months to identify spontaneous recovery. If there is none, an EMG should be performed. If the EMG does not demonstrate significant recovery, surgical intervention should be performed.

In summary, sharp/penetrating injuries with associated neurologic deficit corresponding to the zone of injury should be surgically explored. Compression/crush and avulsion type injuries with associated nerve deficit can be observed with serial examinations up to 3 months.[19] EMG is used to guide next steps in management including continued observation versus surgical intervention.

Goals of Repair

Axonal regeneration is estimated to occur at a rate of 1 mm/day after repair or decompression; it is prudent that muscle reinnervation occurs within 12 to 18 months to maximize return of motor function.[19] After repair or reconstruction of a nerve, there are specific goals from a sensory and motor standpoint. Sensory recovery grading includes:
S0: no sensation
S1: deep cutaneous pain
S2: superficial pain
S3: superficial pain/touch
S4: complete recovery

The goal is "protective sensation," or superficial pain/touch. Return of sensation is determined sequentially using moving and static two-point discrimination as well as Semmes-Weinstein monofilament testing. From a motor standpoint, recovery is graded as follows:
M0: no contraction
M1: perceptible contraction of proximal muscles
M2: perceptible contraction of proximal and distal muscles
M3: contraction against gravity
M4: contraction against resistance
M5: full recovery

The minimal goal of return of motor function is the ability to have antigravity strength. To achieve this goal, the location, type, and extent of nerve injury must be diagnosed as early as possible so that the appropriate repair can be performed to optimize functional outcomes.

Operative Techniques for Nerve Injuries

Direct Repair

During World War I and II, a large number of nerve injuries required surgical intervention; during this time, surgeons explored the wounds, debrided, and often repaired nerves with tension.[25] Since this time, many advancements in the understanding of nerve injuries and optimal repair have been made, including the use of an operating microscope, intraoperative nerve stimulation, and principles of tension-free repairs and/or reconstruction. At the time of exploration, the existing wound/laceration is opened with extensions. Neurolysis is performed, and the proximal and distal ends of the nerve are dissected free of surrounding tissue. If there is significant contamination, insufficient soft tissue wound bed, or the zone of injury is unclear, the nerve ends can be tagged with a suture for later identification and repair. If conditions are suitable, the nerve ends are resected to healthy fascicles and aligned in preparation for repair. An operating microscope (or loupe magnification) and microsurgical instruments are needed, and 8-0, 9-0, or 10-0 monofilament suture can be used to perform epineural repair or grouped fascicular repair depending on the size of the nerve and surgeon preference (Fig. 41.2). Epineural repair is less technically challenging but provides no axonal specificity. Additionally, with mixed nerves, there is the potential for malalignment of the nerve fascicules. The internal vasculature and the appearance of the fascicles can be used to guide orientation and alignment during the repair. Grouped fascicular repair allows for more specificity but is technically demanding and can introduce more intraneural scar with the additional dissection. With either type of repair, it is critical to avoid tension at the nerve repair site because this decreases blood flow and increases scar formation. If there is any tension, slight flexion of the extremity can be performed to relieve this; however, if there is excess tension, one should consider nerve reconstruction. Fibrin glue or nerve conduits can be used at the neurorrhaphy site; fibrin glue has been shown to decrease the number of required sutures and minimize gapping.

Nerve Reconstruction

Nerve gaps of approximately 5 mm can typically be repaired primarily after neurolysis and possible transposition of the nerves; however, larger gaps typically cannot be repaired without undue tension or significant changes in joint position. In these cases, nerve reconstruction should be considered. Nerve reconstruction is also considered when there are additional injuries or medical conditions that necessitate delayed repair as well. Nerve reconstruction should be performed as soon as possible, given the time required for nerve elongation after repair. Reinnervation of muscle before the 12- to 18-month point is necessary to avoid irreversible muscle atrophy and fibrosis.[17] Gaps are largely divided into those <10 mm, 10 to 30 mm, or >30 mm. This distinction is used to make recommendations about the type of nerve graft used for reconstruction. For gaps <10 mm, reconstruction can be performed with any type of conduit. For gaps 10 to 30 mm, it is possible to use allograft or autograft for reconstruction; however, with gaps >30 mm, autograft is recommended.

Autograft is expendable nerve harvested from the injured patient (Fig. 41.3). Common sources include the sural nerve, medial antebrachial cutaneous nerve, lateral antebrachial cutaneous nerve, superficial radial nerve, and posterior interosseus nerve. Donor site is chosen based on the amount of length and diameter of the nerve graft needed for reconstruction; the sural nerve provides the longest and largest-diameter graft. For larger-caliber injured nerves, a single nerve graft is not large enough to support the regeneration of all axons in the proximal nerve stump to the distal nerve stump. In this case, multiple nerve grafts are used to reconstruct the gap.

The use of nerve allografts has increased in popularity related to the lack of donor site morbidity and the readily available supply. These decellularized human nerves undergo proprietary processing to remove all antigenic cells; this allows them to be used without risk of immune reaction.[26] Nerve allograft has been used in a variety of settings, including digital, sensory, motor, and mixed sensory-motor nerves.[22,26] Gaps of less than 30 mm are recommended when choosing to use allograft; however, some studies have demonstrated adequate nerve recovery and favorable outcomes[19] in larger gaps.[26] There is no conclusive evidence supporting their use for gaps greater than 30 mm in major peripheral nerves.

(F) Reconstruction of ulnar nerve partial injury with MABC nerve graft.

Nerve Transfer

Nerve transfers are a technique used to reconstruct a proximal injured nerve by providing distal intact axons from another expendable nerve, for expeditious reinnervation of sensory and motor end organs. Transfers should be performed distal to the site of injury. Confirmation of a functional donor nerve is necessary before transfer. Typically, the donor nerve is dissected as distal as possible to create enough length. The recipient nerve is dissected distal to the injury and close to the end muscle target. A tension-free donor-to-recipient neurorrhaphy is performed. Nerve transfers were popularized after the Oberlin transfer in 1994, whereby ulnar nerve fascicles were transferred to musculocutaneous nerve branches of the biceps to restore elbow flexion.[25] Several nerve transfers have been effective in restoring hand function, particularly when the injuries are above the elbow. Patients with above-elbow ulnar nerve injuries are candidates for distal anterior interosseus nerve (from the pronator quadratus) to the ulnar motor fascicle for restoration of intrinsic hand function.[25] For restoration of ulnar nerve sensory function, the median nerve fascicles of the third webspace can be transferred to the ulnar border of the hand.[27] With distal nerve transfers, there is a decrease in the distance required for regeneration. Another common nerve transfer to improve hand and wrist function involves transfer of the branches of the supinator nerve to the posterior interosseous in the proximal forearm to restore finger, thumb, and wrist extension.[25]

Upper Extremity Nerve Injuries

In the upper extremity, the median, ulnar, radial, and digital nerves are the most frequently injured and will be specifically discussed here. “High” nerve injuries are those that occur above the elbow, and “low” injuries occur below the elbow.

Radial Nerve: Anatomy and Clinical Assessment

The radial nerve is one of the terminal branches of the posterior cord of the brachial plexus. In the upper arm, it passes deep to the long head and between the lateral and medial heads of the triceps. In this region, it is highly susceptible to injury; 22% of all humeral fractures are associated with radial nerve injury.[23] It is a mixed motor and sensory nerve that divides into the superficial radial nerve and posterior interosseous nerve (PIN).[23] The superficial radial nerve provides sensation to the dorsoradial aspect of the hand; the radial nerve proper and PIN nerve provide motor innervation to the triceps; brachialis; brachioradialis; and extensors of the wrist, fingers, and thumb.[23] Injury is often heralded by loss of sensation in the distribution of the nerve as well as inability to actively extend the wrist, fingers, and thumb.

Among patients with closed neuropraxic radial nerve injuries related to humeral fractures, spontaneous recovery has been observed in 60% to 92% of patients; however, among humeral fractures associated with high-velocity gunshot wounds, vascular injuries, or other penetrating trauma, surgical exploration is recommended.[23]

Ulnar Nerve: Anatomy and Clinical Assessment

The ulnar nerve travels between the medial epicondyle and olecranon as it crosses the elbow and enters the medial forearm and through the flexor carpi ulnaris. It continues distally, running alongside the ulnar artery in between the flexor digitorum superficialis (FDS) and profundus (FDP). It is responsible for sensation along the volar small finger and one-half of the ring finger as well as the dorsoulnar hand. From a motor standpoint, it innervates the flexor carpi ulnaris, FDP of the ring and small fingers, adductor pollicis, and intrinsic hand muscles. Classically, patients will present with loss of sensation and hand weakness manifested by an intrinsic minus clawing position (hyperextension of the metacarpophalangeal joint and flexion of the proximal interphalangeal joints) of the small and ring fingers. Additionally, patients will also have deficits in thumb adduction and finger adduction and abduction; this loss of intrinsic hand function results in decreased pinch and grip strength.[27] Detection of ulnar nerve deficits can be challenging in the presence of Martin-Gruber anastomosis between the ulnar and median nerves in the forearm; under such circumstances, muscles normally innervated by the ulnar nerve are supplied by the median nerve, producing a heterogenous clinical picture.[27]

Median Nerve: Anatomy and Clinical Assessment

The median nerve lies deep in the proximal forearm as it runs between the heads of the pronator teres, but it becomes more superficial at the wrist, placing it at increased risk during penetrating injuries (lacerations) and blunt trauma (MVC). The median nerve is responsible for sensation of the volar thumb, index, middle, and one-half of the ring finger; it provides motor innervation to the pronator teres, flexor digitorum, flexor pollicis brevis, flexor carpi radialis, palmaris longus, and thenar musculature including the abductor pollicis brevis. The median nerve is of critical importance to hand sensation, and injury results in loss of sensation over the volar fingertips as well as decreased thumb motion, including opposition and palmar abduction. Because of its location, the median nerve is often injured in conjunction with the flexor tendons. Sharp penetrating injuries in the location of the median nerve with associated deficits should be explored within a week of injury to increase the chances of primary repair.[28]

Surgical Treatment of Median, Ulnar, and Radial Nerves

At the time of exploration, existing lacerations are extended proximal and distal to allow full exploration and neurolysis if needed. Large nerves can be repaired with loupe magnification or operating microscope using 6-0 Prolene or 8-0/9-0 nylon. Because the median, ulnar, and radial nerves are mixed motor and sensory, it is critical to use the orientation and appearance of grouped fascicles and blood vessels to align the nerve ends and perform a tension-free epineural repair (see Fig. 41.3). The ulnar nerve internal topography has been studied extensively with distinct organization of the motor and sensory components. The ulnar nerve is often injured with adjacent tendons and/or the ulnar artery. Slight wrist flexion may be used to facilitate direct repair in certain circumstances.[28] If too much tension or too much flexion is required, reconstruction with autograft or allograft is needed. The autograft of choice is the sural nerve, which is harvested from the lower extremity and cut into cables of the appropriate length to bridge the gap (Figs. 41.4 and 41.5). Concomitant arterial injuries should be repaired with upper extremity fasciotomies performed if there is prolonged ischemia or concern for compartment syndrome.

Outcomes of Median, Ulnar, and Radial Nerve Injuries

Motor and sensory recovery are affected by the age of the patient (younger age better than older), site of injury (proximal worse than distal), and time delay to surgery.[27,28] The best possible outcomes have been achieved with direct primary repair. Among ulnar nerve injuries treated with neurolysis alone, M3 or greater motor function is achieved in 92% of cases.[27] Because intrinsic hand muscle function is difficult to restore after injury, median nerve repairs have better reported and functional outcomes compared with the ulnar nerve.[27] In a meta-analysis including 623 patients who underwent median and ulnar nerve injury repair, 43% regained S3+ sensory and 52% regained >M4 motor recovery; the authors identified that younger patients were four times more likely to recover motor function and the ulnar nerve was 70% less likely to have motor recovery compared with the median nerve.[27,29] Examination of >1000 nerve injuries at a large single-center institution demonstrated good recovery (S3/M4) among 80% to 100% of radial nerve injury patients, with poorer outcomes among ulnar nerve patients.[20] Because of the relative proximal innervation of the wrist, hand, and finger extensors, radial nerve repairs have better potential for functional recovery than do other peripheral nerves. Despite this, results are mixed; among radial nerve injuries directly repaired within 6 months of injury, good to fair results are reported in 60% of patients, whereas a series of combined radial nerve (proximal) and PIN (distal) nerve injuries (repair and reconstructions) demonstrated a 42% failure rate.[23] In all cases of failed or incomplete recovery after median, ulnar, or radial nerve injuries, tendon transfers can be performed using remaining expendable muscles to perform critical hand functions.

Digital Nerves: Anatomy, Assessment, and Treatment

Each digit has a radial and ulnar nerve along the volar aspect that is responsible for sensation. The digital nerves lie volar (palmar) to

the digital arteries and along the flexor tendons. Digital nerves are commonly injured in conjunction with tendon and bone, with mechanisms including sharp laceration, stretch, and compression.

Careful history and physical can elucidate the presence of a digital nerve injury. Both the radial and ulnar sides of the digit or thumb should be tested individually and compared with the uninjured digits. Treatment options include observation and surgical exploration. If there is a high suspicion of complete transection, surgical exploration is recommended; however, 10% of patients at the time of exploration may not have a complete transection and may undergo neurolysis and closure.[30] Among those who choose surgery, exploration within the first week after injury provides the best opportunity for direct repair. The goal with surgical repair is to ensure axonal continuity and achieve protective sensation; in the most optimal of conditions, “normal sensation” can be obtained. A tension-free direct repair proceeds with debridement of the proximal and distal nerve ends to healthy fascicles and an epineural repair with 8-0 or 9-0 microsuture. Up to 11% of direct nerve repairs are considered “failures.”[30] With concomitant tendon or bone injuries, the surgeon must consider the period of postoperative immobilization and time to initiation of the appropriate rehabilitation protocol.

If the presentation or diagnosis is delayed, nerve reconstruction with autograft, allograft, or conduits is possible. Traditionally, autograft is the gold standard and recommended for any gap size, but especially those >3 cm. The injured proximal and distal nerve ends are prepared, and a graft of appropriate size and length is chosen for reconstruction; the graft is directly sutured to the nerve ends using 8-0 or 9-0 microsuture to create a tension-free repair. In a systematic review from 2020 including a heterogenous group of digital nerve injuries, 95% had good to excellent recovery and 28% regained normal recovery.[30] Decellularized human nerve allografts are increasingly being used for variable digital nerve injury gaps (10–70 mm) with 69% to 80% of patients reporting good or excellent recovery in a recent review.[30] Commercially available conduits are available and composed of biocompatible materials including collagen, chitosan, and polyglycolic acid. Conduits are typically used when the gap is less than 15 mm and the surgeon prefers to avoid a donor site to harvest autologous nerve. During this procedure, the proximal and distal nerve ends are intubated into the conduit using sutures.[30] The conduit provides an enclosed space for the proximal axons to grow toward the distal end and has been associated with good to excellent recovery.[30]

Lower Extremity Nerve Injuries

Injuries to the lower extremity peripheral nerves are less common than those to the upper extremity. Within the lower extremity, the peroneal, tibial, and sciatic nerves are the most injured. As with upper extremity nerve injuries, lower extremity injuries can result in chronic pain, loss of sensation, and loss of motor function of the extremity.

Tibial Nerve: Anatomy, Assessment, and Treatment

The tibial nerve is one of the terminal branches of the sciatic nerve and is responsible for sensation on the plantar aspect of the foot as well as motor function of the posterior leg compartment including the ankle and toe plantar flexors and intrinsic muscles.[31]

Surgical options after tibial nerve injury include neurolysis, nerve repair, nerve reconstruction, or nerve transfer. The sural nerve is the most used autograft. Nerve transfers using the saphenous nerve for sensation and obturator nerve for motor function have been described for tibial nerve injuries.[31]

Peroneal: Anatomy, Assessment, and Treatment

The peroneal nerve is one of the terminal branches of the sciatic nerve. It crosses lateral to the head of the fibula and gives rise to the superficial and deep peroneal nerves. The superficial peroneal nerve is a mixed motor-sensory nerve; it innervates the lateral compartment muscles (peroneus brevis and longus) and provides sensation to the lower one-third of the anterior calf and lateral dorsal foot (except the first webspace). The deep peroneal nerve is also a mixed motor-sensory nerve that innervates the muscles of the anterior compartment and provides sensation to the first dorsal webspace of the foot. Injuries to the common peroneal nerve (CPN) result in foot drop, altered gait, inability to evert the ankle, and sensory loss along the distal anterior calf and dorsal foot. Because of its position along the fibular head, the CPN is in a vulnerable position and susceptible to injury.

The CPN is the most common lower extremity nerve that is injured after trauma, representing 10% to 21% of peripheral nerve injuries.[32] Mechanisms of injury include traumatic knee dislocation/fractures, gunshot wounds, lacerations, and other crush injuries. CPN injuries are difficult to manage and are often associated with poor outcomes. Outcomes are predicated on several factors including the mechanism of injury, zone of injury, associated injuries, delay in treatment of nerve injury, length of damaged nerve, and other medical comorbidities. After CPN injuries, two-thirds of patients report difficulty walking and neuropathic pain.[32] Nonoperative treatment ranges from observation, to physical therapy, to ankle-foot orthoses. Operative intervention for transected nerves includes direct repair or reconstruction with autograft or allograft.[32] If the nerve is transected, direct repair should be performed. Functional recovery ≥M3 was achieved in (63/80) 78.8% of patients who underwent primary repair.[32] If there is a gap, peroneal nerve reconstruction with nerve grafting should be performed; however, variable outcomes have been reported.

If patients are not able to regain function of the anterior tibialis 18 months after observation or surgical intervention, a posterior tibialis tendon to anterior tibialis transfer can be performed to facilitate foot dorsiflexion. Patients stand to regain up to 42% of strength compared with the contralateral side with this transfer.[32] Some surgeons may consider performing concurrent neurolysis/nerve reconstruction and posterior tibial tendon transfer if the presentation is delayed or the nerve gap significant.

Outcomes After Tibial and Peroneal Nerve Repair and/or Reconstruction

Tibial nerve injuries that require neurolysis alone have the best outcomes.[31] Tibial nerves amenable to direct repair resulted in 89% of patients achieving a good outcome.[31] In a meta-analysis examining outcomes after nerve transfer among 30 patients, 71% achieved a good outcome.[31]

In a meta-analysis examining traumatic peroneal nerve injuries, surgical intervention was recommended if no spontaneous improvement was seen 6 months after the injury, but shorter preoperative times were associated with improved outcomes.[32] Among 465 patients who underwent peroneal nerve reconstruction, 49% achieved >M3 recovery; mean nerve graft length was 7 cm, but shorter grafts improved outcomes.[32] Nerve transfers for common peroneal injuries have been described; tibial nerve branches have been successfully transferred to the distal CPN in an end-to-end fashion yielding >M3 function for 62.9% of patients in one meta-analysis.[32]

Summary of Peripheral Nerve Injuries

Peripheral nerve injuries of the upper and lower extremities are extremely common and can have a profound impact on patient quality of life. Careful history, physical examination, and early diagnosis are key to appropriate intervention. Mechanism of injury, preoperative interval, patient age, direct repair versus reconstruction, gap length, and the use of allograft or autograft all affect outcome. Injuries associated with sharp lacerations have better outcomes than those associated with blast and gunshot wounds.[23,27,31] Delay in time between injury and repair or reconstruction is associated with poor motor recovery.[23,27,31] Nerve injuries managed by direct repair have better reported outcomes than those where reconstruction is required. Under circumstances of reconstruction, poor recovery of sensory and motor function is associated with gaps greater than 3 cm (regardless of graft material).[31] Because of the longer distance the regenerating axons must travel to get to end organs after nerve injuries, proximal nerve injuries have worse outcomes than do distal injuries.[22,26,33]

SPINE EMERGENCIES

Spinal emergencies are defined as any injury to the spinal column, spinal cord, or nerve roots that requires emergent or urgent treatment. The most common reason for spinal emergencies is some form of traumatic spinal injury, which comprises both fractures to the spinal column, where the spinal column is injured with or without damage to the spinal cord, and spinal cord injury (SCI), where the spinal cord itself is damaged. Importantly, fractures without SCI are still emergent conditions, where the spine is unstable, and without fixation, injury to the spinal cord can occur with minor movement. When the spinal cord itself is damaged, SCI can leave patients with debilitating neurologic deficits, leading to permanent disability with concomitant societal and economic effects. SCI primarily affects young adult males, with trauma being the most common etiology. According to recent demographic and epidemiologic insights, ~450,000 persons living in the United States are permanently disabled because of traumatic SCI, with ~11,000 new cases each year. Notably, the incidence in the United States exceeds that of many other countries. The pattern of injury exhibits a bimodal age distribution, with the initial peak affecting young adults and accounting for approximately 50% of new cases, whereas the second peak primarily involves individuals over the age of 60. The financial burden is substantial, with direct medical expenses ranging from $500,000 to $2 million over the lifetime of an affected individual. Remarkably, alcohol is implicated in at least 25% of traumatic SCI cases.

Certain underlying spinal conditions may predispose individuals to becoming susceptible to traumatic SCI, including cervical degeneration/spondylosis, atlantoaxial instability, congenital conditions, osteoporosis, and spinal arthropathies, such as ankylosing spondylitis (AS) or rheumatoid arthritis. After acute SCI, patients are at risk of further neurologic deterioration because of secondary injury to the spinal cord either by inadvertent manipulation of the spine in the setting of an unstable spinal column injury or failure in medical management to maintain adequate perfusion of the spine. Timely intervention in SCI is paramount. Fast and appropriate management during the early stages of injury, whether it occurs in a prehospital setting or at a healthcare facility, can help prevent further damage to the spinal cord, reduce the risk of complications, and improve the chances of functional recovery. The current guidelines advocate for surgical intervention to be performed within a 24-hour window from the time of injury. In patients with incomplete injuries with salvageable neurologic function, the urgency for surgical treatment is even greater, with some authors suggesting surgical intervention in $<$8 hours.

Although trauma is likely the most common cause of spinal emergencies, nontraumatic conditions can also lead to spinal emergencies. Around 372,000 persons in the United States live with nontraumatic spinal injuries. Patients with degenerative pathology can present with symptoms of spinal cord compression as a consequence of cervical spondylotic myelopathy or disc herniation. In addition, patients with spinal tumors may present with acute or subacute neurologic deterioration that requires urgent medical, surgical, or radiation therapy. Other etiologies of nontraumatic spinal emergencies include inflammatory/autoimmune conditions such as multiple sclerosis and neuromyelitis optica as well as infections such as epidural abscess. High-income countries tend to have a higher proportion of cases secondary to degenerative conditions and tumors, whereas in developing countries, infection contributes to the majority of nontraumatic spinal emergencies. Vascular disorders may also result in spinal emergencies requiring urgent management, including spontaneous hematomas, arteriovenous malformations (AVMs), and spinal cord infarction caused by thrombotic, embolic, vasoocclusive, or hemorrhagic etiologies. Other miscellaneous conditions that require emergent treatment include amyotrophic lateral sclerosis and primary lateral sclerosis as well as metabolic causes such as subacute combined degeneration caused by vitamin B_{12} deficiency.

The current chapter provides an overview of select spinal emergencies and highlights the nuances of prompt recognition and definitive management, without delving into nuances of surgical technique. It is important to clarify that the focus of this chapter is on all spinal emergencies for the targeted audience of general surgeons and acute care surgeons caring for the critically injured patient, rather than neurosurgeons or orthopedic surgeons. Herein, we describe three major areas of spinal emergencies, including (1) an overview of SCI, (2) spinal emergencies caused by traumatic events, and (3) spinal emergencies caused by nontraumatic events. Although we recognize this is not an exhaustive list of all spinal emergencies, the discussion that follows addresses common areas of spinal emergencies most relevant to the general surgeon.

Spinal Cord Injury General Management

Spinal Anatomy

The spinal cord originates at the base of the brainstem, specifically the medulla, and commences at the first cervical vertebra, just distal to the craniocervical junction. The spinal cord terminates at L1–L2 in adults and as low as L3–L4 in children, where it is called the *conus medullaris.* Extending from the apex of the conus medullaris is the filum terminale, an extension of the pia mater that attaches to the posterior surface of the coccyx. After the spinal cord terminates, the cauda equina travels from approximately L1–L2 to the sacrum, carrying lumbar and sacral nerve roots that control lower extremity, bowel/bladder, and sexual function.

The spinal cord generates 31 pairs of spinal nerves that predominantly innervate the trunk and limbs. These spinal nerves are categorized into cervical (8 pairs), thoracic (12 pairs), lumbar (5 pairs), and sacral (5 pairs each), along with one pair of coccygeal nerves. In the cervical spine there are seven vertebrae but eight nerve roots, which is why the lower-level roots exit at each level (i.e., the C5 root exits in the C4/5 foramen, the C6 root exits at the C5/6 foramen, and so on). After C7/T1, when the thoracic spine starts, the roots exit at the same level (i.e., the T1 root exits at the T1/2 foramen, the L2 root exits at the L2/3 foramen, and so on). The spinal nerves have two roots, a ventral or motor root and a dorsal or sensory root. The dorsal root has a distinctive swelling called the *dorsal nerve root ganglion,* which contains cell bodies of pseudounipolar sensory neurons. At the conus medullaris, nerve roots coming from the lower lumbar, sacral, and coccygeal nerves form a bundle of nerves known as *cauda equina.* The spinal cord is enveloped from outermost to innermost by the dura mater, arachnoid mater, and pia mater. The space situated between the dura mater and the wall of the vertebral canal is referred to as the *extradural* or *epidural space,* which is filled with copious epidural veins. The area between the dura mater and arachnoid mater is known as the *subdural space,* and the subarachnoid space lies between the arachnoid mater and pia mater, containing CSF. It is most often the epidural space that gets invaded by fracture fragments, hematoma, and tumors, which leads to epidural spinal cord compression. Occasionally, intradural pathology can also cause cord compression.

The spinal cord is nourished by one anterior spinal artery and two posterior spinal arteries. The anterior spinal artery runs along the front median fissure, whereas the two smaller posterior spinal arteries pass through the posterolateral sulcus on either side. In the cervical spine, these spinal arteries primarily branch from the vertebral arteries, which ascends from C6–C2 in the foramen transversarium, though it can enter early at C7 or later at C5 and above. Farther down the spinal cord, blood supply is provided by radicular arteries that reach both the cord and the roots of the spinal nerves. These radicular arteries branch from various sources, including the vertebral, cervical, intercostal, lumbar, and sacral arteries. The most noteworthy radicular contributor to the anterior spinal artery, known as the *artery of Adamkiewicz,* arises from the left posterior intercostal artery and is located between the T9 and T12 vertebrae. The spinal cord's venous drainage system is organized into a network consisting of six longitudinal channels: an anteromedian vein, a posteromedian vein, and a pair of anterolateral and posterolateral veins. The venous blood collected in these veins ultimately flows into the venous plexus and radicular veins, which, in turn, discharge into segmental veins.

Protecting these delicate neural elements is the spinal column, or the vertebral column, which consists of 33 vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 4 coccygeal. Anteriorly, a typical vertebra consists of a solid cylindrical body attached posteriorly to two pedicles connecting to flat laminae. Extending outward are transverse processes to which muscles and ligaments attach. The spinous process projects posteriorly, often palpable along the spine. Additionally, each vertebra features superior and inferior articular processes that form facet joints, facilitating spinal movement. Adjacent vertebrae create intervertebral foramina, allowing for the passage of spinal nerves and blood vessels.

Initial Management of Spinal Cord Injury

The acute management of SCI adheres to the concept of "time is spine"—a key tenet that guides interventions.[34] Concern for a cervical or thoracic SCI should prompt immediate immobilization of the spine at the scene, which can be achieved through application of a rigid cervical collar or use of supportive blocks and straps on a backboard. Similarly, when dealing with unstable fractures, immobilization of the spine should be ensured while transferring the patient with multiple people in a "logroll" fashion. Most commonly in blunt trauma, efforts to maintain immobilization should be made, provided that it does not impede essential resuscitation efforts. These measures are meant to minimize the risk of exacerbating spinal cord damage by excess movement that cannot be supported by an unstable spinal column or damaged spinal cord.

After immobilization, ATLS guidelines should be meticulously applied to ensure the assessment and management of the injured patient. In patients with compromised airways, it is imperative to secure a definitive airway while ensuring continuous spinal immobilization during the intubation process. Additionally, cervical and thoracic injuries may impede proper innervation of vital respiratory muscles, including the diaphragm, intercostal muscles, and abdominal muscles, which can result in decreased respiratory drive, hypoxemia, and hypercarbia. Approximately one-third of patients with injuries to the cervical spine require intubation within the first day after injury.

In addition to the inflammatory response contributing to secondary SCI, spinal cord blood flow reduction can exacerbate the primary SCI. Patients with SCI in the setting of polytrauma may also suffer from dehydration, extraspinal injuries, and vasogenic shock. Maintaining adequate spinal cord flow is often recommended for nonsurgical management for an SCI, but there are no direct measurements of spinal blood flow. Knowing that flow does not equal pressure, it is often accomplished by keeping MAP above 85 mm Hg, or at least 10 points higher than their baseline, relevant for patients with known baseline uncontrolled hypertension. After ensuring euvolemia, vasopressors are sometimes needed. Furthermore, the severity of the SCI correlates with the need for vasopressors based on the extent of injury: complete cervical SCI, 90%; incomplete cervical SCI, 52%; complete thoracic SCI, 33%; and incomplete thoracic, 25%. Sometimes, vasopressors cannot be safely used because of competing clinical priorities (e.g., impulse control for aortic or cardiovascular injuries, myocardial ischemia, emergency hypertensive crisis, intracranial hemorrhage risk).

In patients with SCI in the cervical and upper thoracic regions (above T6), damage to the sympathetic tracts within the intermediolateral column can precipitate neurogenic shock. This condition is characterized by bradycardia and hypotension caused by reduced vascular tone resulting from unopposed parasympathetic vagal activity. Neurogenic shock exacerbates the ischemic burden on the already vulnerable injured spinal cord, leading to global hypoperfusion—a situation further compounded in cases of concurrent blood loss, as seen in polytrauma patients. In conjunction with crystalloid volume resuscitation, vasopressors may be considered to counteract peripheral vasodilation.

Neurologic Examination

Patients with SCI can manifest with varying degrees of severity, classified as either complete, meaning no neurologic function below the level of injury, or incomplete, with preservation of some motor and/or sensory function below the level of injury. The assessment and description of the severity of SCI often adhere to the American Spinal Injury Association (ASIA) scoring system, a universally recognized tool. This system allows for a comprehensive evaluation of the motor and sensory deficits, facilitating a standardized and effective means of characterizing the extent of the SCI. *One of the most important things for general surgeons and acute care surgeons caring for injured patient with acute SCI is to be familiar with the neurologic and spinal examination and communicate findings and future changes to the spine surgery team.*

First, the GCS (described earlier in the "Traumatic Brain Injury" section) is used to assess the level of awareness in patients with impaired consciousness and concomitant brain injury. A quick mental status examination is equally important to screen for abnormalities that may warrant further investigations, and it involves asking for orientation to time, place, and person.

The assessment of muscle strength adheres to the following muscle grading system (0–5): 0, no muscle contraction is seen or identified with palpation; 1, flicker of contraction insufficient to produce any movement; 2, active movement with gravity eliminated; 3, active movement against gravity with no resistance; 4, active movement against gravity with moderate resistance; and 5, normal muscle strength against gravity and with full resistance. Testing muscle strength should be done in an orderly manner, aiming to differentiate proximal/distal and left/right muscle weakness. Motor examination of the upper extremity includes shoulder abduction (C5), elbow flexion (C5–C6), elbow extension (C6–C7), wrist extension (C6–C7), wrist flexion (C7–C8), finger flexion (C8), finger extension (C8), and finger abduction (T1). In the lower extremity, the following movements are tested: hip flexion (L2–L3), hip extension (L4–L5), knee flexion (L5–S1), knee extension (L3–L4), ankle dorsiflexion (L4–L5), big toe extension (through extensor hallucis longus muscle, L5), and ankle plantar flexion (S1–S2).

Reflexes are then tested. The biceps and brachioradialis reflexes are mediated by C5–C6, the triceps reflex by C6–C7, knee jerk by L3–L4 (mainly L4), and the ankle jerk S1 nerve root. Reflexes are graded according to the following: 0 = absent, 1 = reduced (hypoactive), 2 = normal, 3 = increased (hyperactive), and 4 = clonus. Other reflexes include the plantar response where the sole of the patient's foot is stroked with a blunt and narrow surface object such as the handle of a reflex hammer. A normal response is whenever all toes flex, and it is called a *flexor plantar response;* an abnormal response occurs when the great toe dorsiflexes and the other toes fan out, indicating damage to the upper motor neuron pathways, and is known as the *Babinski sign.* Another indicator of upper motor neuron weakness is Hoffmann sign, elicited by flipping the fingernail of the middle finger, resulting in an involuntary flexion of the interphalangeal joint of the index finger and thumb. In some cases, the abdominal reflexes (T8–T12) and cremasteric reflex (L1–L2) are performed to localize the level of injury. Another key aspect of the spinal exam is the bulbocavernosus reflex (S2–S4), which involves monitoring of the anal sphincter contraction in response to squeezing the glans of the penis or clitoris or tugging on an indwelling Foley catheter. The absence of the bulbocavernosus reflex indicates that the patient is still in spinal shock, and the current examination cannot be interpreted as the real evaluation of neurologic function.

The sensory examination usually consists of pinprick sensation to determine the sensory level, comparing proximal with distal and right/left upper/lower extremities. In some case such as Brown-Sequard syndrome, an extensive sensory examination is required and consists of pain and temperature and vibration and proprioception. A rectal examination is similarly important to assess the sensation of the anal orifice and the contraction of the external anal sphincter. The absence of tone and volitional squeeze of the anal sphincter may indicate SCI. Although a detailed neurologic examination may take time, it localizes and assesses the severity of the SCI before surgical treatment.

The ASIA Impairment Scale categorizes SCI into five main grades: ASIA A, B, C, D, and E. ASIA A represents the most severe injury, denoting a complete injury manifesting in a total loss of motor and sensory function below the level of the injury, with no sensation in the anal and perineal regions (S4–S5). Additionally, there is an increased tendency for urinary retention and bladder distention. *Sacral sparing* is a term that applies to preservation of sacral cord function in the form of intact rectal tone or intact rectal sensation, which is associated with a better prognosis. Fig. 41.6 shows the ASIA score sheet commonly used by spine surgeons.

Incomplete SCI ranges from ASIA B to ASIA D. ASIA B signifies an incomplete injury with preserved sensory function but no motor function below the injury level, with sacral sparing. ASIA C indicates an incomplete injury but includes some motor function below the injury level, with most muscles graded less than 3 on the motor scale. ASIA D is another incomplete injury, but in this case, there is preserved motor function below the injury level, with most muscles graded at 3 or higher. Lastly, ASIA E denotes a normal neurologic status with no deficits, signifying the absence of any SCI. A mnemonic-based way to remember the scale is that ASIA E represents normal motor/sensory function, remembered with the word E = everyone, as most people do not have an SCI. Conversely, ASIA A is such that A = albatross, denotating rarity, that SCI is a rare event.

In the immediate aftermath of a severe SCI, it is important to note the presence of spinal shock, which may mean the current examination cannot be trusted. Spinal shock encompasses complete loss of motor and sensory function below the injury level, along with the absence of deep tendon reflexes and the bulbocavernosus reflex. Particularly, the absence of the bulbocavernosus reflex complicates accurate prognostication during this phase because if a bulbocavernosus reflex is not present, the patient is in shock, and a future neurologic examination may improve beyond the current state. Traditionally, return of the bulbocavernosus reflex has been regarded as an indicator marking the end of spinal shock. Even in an ASIA A complete injury, a bulbocavernosus reflex should be present, indicating the patient is not in spinal shock.

Spinal shock is inherently transient, and its temporal progression can be delineated by the gradual return of spinal reflexes. The neurologic progress typically commences with the bulbocavernosus reflex, which may reappear as early as 1 hour after the injury. Subsequently, the anal cutaneous reflex and the plantar reflex may also gradually return. It is crucial to differentiate between spinal shock and neurogenic shock, as the latter typically occurs with injuries at cervical and high thoracic vertebral levels (above T6) and is characterized by sympathetic dysfunction, leading to hypotension, hypothermia, and bradycardia. Importantly, the occurrence of these two types of shock is not mutually exclusive, can overlap in individuals with SCI, and can also be challenging to differentiate which exact pattern of shock is present.

Various patterns of SCI can result from different mechanisms of injury. *Central cord syndrome* often occurs in older individuals suffering from hyperextension injury exacerbating preexisting cervical spondylosis or central canal stenosis caused by hypertrophied ligamentum flavum posteriorly or the presence of disc herniations and/or osteophytes anteriorly. The physical examination displays greater motor impairment in the upper extremities, especially the distal aspects, compared with the lower extremities, which aligns with the somatotopy of the arms in the spinal tracts. Central cord syndrome can also lead to bladder dysfunction and varying degrees of sensory loss in the lower body. *Anterior cord syndrome* involves damage to the anterior two-thirds of the spinal cord.[35] It can result from a vascular injury or a direct mechanical injury, such as disc or bone fragment retropulsion. Anterior cord syndrome leads to complete motor paralysis and loss of pain and temperature sensation, but preservation of tactile position and vibration sense. *Brown-Sequard syndrome* occurs because of unilateral damage to the dorsal column, corticospinal tract, and spinothalamic tract. Patients experience ipsilateral weakness and loss of vibration and proprioception, whereas contralateral loss of pain and temperature sensation occurs about two spinal levels below the injury. Common causes include ballistic and penetrating injuries. *Posterior cord syndrome* is a rare condition involving the loss

Muscle Function Grading
0 = Total paralysis
1 = Palpable or visible contraction
2 = Active movement, full range of motion (ROM) with gravity eliminated
3 = Active movement, full ROM against gravity
4 = Active movement, full ROM against gravity and moderate resistance in a muscle specific position
5 = (Normal) active movement, full ROM against gravity and full resistance in a functional muscle position expected from an otherwise unimpaired person
NT = Not testable (i.e. due to immobilization, severe pain such that the patient cannot be graded, amputation of limb, or contracture of > 50% of the normal ROM)
0*, 1*, 2*, 3*, 4*, NT* = Non-SCI condition present [a]

Sensory Grading
0 = Absent **1** = Altered, either decreased/impaired sensation or hypersensitivity
2 = Normal **NT** = Not testable
0*, 1*, NT* = Non-SCI condition present [a]

[a] Note: Abnormal motor and sensory scores should be tagged with a "*" to indicate an impairment due to a non-SCI condition. The non-SCI condition should be explained in the comments box together with information about how the score is rated for classification purposes (at least normal / not normal for classification).

When to Test Non-Key Muscles:
In a patient with an apparent AIS B classification, non-key muscle functions more than 3 levels below the motor level on each side should be tested to most accurately classify the injury (differentiate between AIS B and C).

Movement	Root level
Shoulder: Flexion, extension, adbuction, adduction, internal and external rotation **Elbow:** Supination	C5
Elbow: Pronation **Wrist:** Flexion	C6
Finger: Flexion at proximal joint, extension **Thumb:** Flexion, extension and abduction in plane of thumb	C7
Finger: Flexion at MCP joint **Thumb:** Opposition, adduction and abduction perpendicular to palm	C8
Finger: Abduction of the index finger	T1
Hip: Adduction	L2
Hip: External rotation	L3
Hip: Extension, abduction, internal rotation **Knee:** Flexion **Ankle:** Inversion and eversion **Toe:** MP and IP extension	L4
Hallux and Toe: DIP and PIP flexion and abduction	L5
Hallux: Adduction	S1

ASIA Impairment Scale (AIS)

A = Complete. No sensory or motor function is preserved in the sacral segments S4-5.

B = Sensory Incomplete. Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-5 (light touch or pin prick at S4-5 or deep anal pressure) AND no motor function is preserved more than three levels below the motor level on either side of the body.

C = Motor Incomplete. Motor function is preserved at the most caudal sacral segments for voluntary anal contraction (VAC) OR the patient meets the criteria for sensory incomplete status (sensory function preserved at the most caudal sacral segments S4-5 by LT, PP or DAP), and has some sparing of motor function more than three levels below the ipsilateral motor level on either side of the body. (This includes key or non-key muscle functions to determine motor incomplete status.) For AIS C – less than half of key muscle functions below the single NLI have a muscle grade ≥ 3.

D = Motor Incomplete. Motor incomplete status as defined above, with at least half (half or more) of key muscle functions below the single NLI having a muscle grade ≥ 3.

E = Normal. If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

Using ND: To document the sensory, motor and NLI levels, the ASIA Impairment Scale grade, and/or the zone of partial preservation (ZPP) when they are unable to be determined based on the examination results.

AMERICAN SPINAL INJURY ASSOCIATION
INTERNATIONAL STANDARDS FOR NEUROLOGICAL CLASSIFICATION OF SPINAL CORD INJURY
ISCOS INTERNATIONAL SPINAL CORD SOCIETY
Page 2/2

Steps in Classification
The following order is recommended for determining the classification of individuals with SCI.

1. Determine sensory levels for right and left sides.
The sensory level is the most caudal, intact dermatome for both pin prick and light touch sensation.

2. Determine motor levels for right and left sides.
Defined by the lowest key muscle function that has a grade of at least 3 (on supine testing), providing the key muscle functions represented by segments above that level are judged to be intact (graded as a 5).
Note: in regions where there is no myotome to test, the motor level is presumed to be the same as the sensory level, if testable motor function above that level is also normal.

3. Determine the neurological level of injury (NLI).
This refers to the most caudal segment of the cord with intact sensation and antigravity (3 or more) muscle function strength, provided that there is normal (intact) sensory and motor function rostrally respectively.
The NLI is the most cephalad of the sensory and motor levels determined in steps 1 and 2.

4. Determine whether the injury is Complete or Incomplete.
(i.e. absence or presence of sacral sparing)
If voluntary anal contraction = ***No*** *AND all S4-5 sensory scores =* ***0***
AND deep anal pressure = ***No****, then injury is* ***Complete.***
Otherwise, injury is ***Incomplete****.*

5. Determine ASIA Impairment Scale (AIS) Grade.
Is injury Complete? If YES, AIS=A
NO ↓
Is injury Motor Complete? If YES, AIS=B
NO ↓ (No=voluntary anal contraction OR motor function more than three levels below the motor level on a given side, if the patient has sensory incomplete classification)

Are at least half (half or more) of the key muscles below the neurological level of injury graded 3 or better?
NO ↓ AIS=C **YES ↓ AIS=D**

If sensation and motor function is normal in all segments, AIS=E
Note: AIS E is used in follow-up testing when an individual with a documented SCI has recovered normal function. If at initial testing no deficits are found, the individual is neurologically intact and the ASIA Impairment Scale does not apply.

6. Determine the zone of partial preservation (ZPP).
The ZPP is used only in injuries with absent motor (no VAC) OR sensory function (no DAP, no LT and no PP sensation) in the lowest sacral segments S4-5, and refers to those dermatomes and myotomes caudal to the sensory and motor levels that remain partially innervated. With sacral sparing of sensory function, the sensory ZPP is not applicable and therefore "NA" is recorded in the block of the worksheet. Accordingly, if VAC is present, the motor ZPP is not applicable and is noted as "NA".

FIGURE 41.6 (A–B) ASIA score sheet.

of function in the posterior column, responsible for deep touch, proprioception, and vibration sensation. Patients can still ambulate but rely heavily on visual input for spatial orientation.

Imaging for Spinal Cord Injury

Imaging plays a pivotal role in the initial assessment of patients with suspected SCI. The selection of the appropriate imaging is contingent on the patient's clinical presentation and the accessibility of imaging resources at the trauma center. CT and MRI are currently the most used after the initial phase of the injury.[36]

CT is usually used as the primary imaging modality, which provides a detailed visualization of the osseous anatomy and associated fractures, traumatic disc herniations, and epidural/subdural hematomas in the spinal canal. CT has a sensitivity of 97% to 100% in identifying cervical spine fractures compared with standard lateral x-rays, which have a sensitivity of only 63%. In thoracolumbar trauma, CT was associated with sensitivity ranging from 78.1% to 100%; x-rays had sensitivity of 32% to 74%. However, CT imaging is not without problems. Concerns for a significant radiation exposure as well as artifacts from image acquisition in the setting of instrumentation from previous spine fusion can occur.

The gold standard of imaging in evaluating patients with SCI remains the MRI, which provides visualization of the spinal cord and neural elements. Through its multiplanar capabilities, MRI offers useful information regarding spinal cord compression, ligamentous injuries, disc herniation, spinal cord contusions, hemorrhage, swelling, and cord edema as well as injuries to the paraspinal tissues. The T2 sequence is the most often used, given the clear ability to see hyperintense CSF surrounded by a hypointense spinal cord. One downside of MRI includes time taken to acquire imaging. Constant communication of the MRI technician with the radiologist and spine surgeon is recommended to ensure the efficient acquisition of these images. MRI is also contraindicated in the presence of cardiac pacemaker and metallic foreign bodies.

Other less studied images in the setting of SCI include MRI protocols including diffusion-weighted imaging (DWI), functional MRI, and perfusion MRI, all of which were reportedly used to assess for the extent of the SCI. When MRI is unavailable, CT myelography with intrathecal soluble contrast injection can be used when a compromise of the spinal canal is suspected. In the setting of cardiac stents, shrapnel, or spinal implants with heavy artifact, an emergent CT myelogram is necessary to visualize the neural elements.

Traction

In the setting of an SCI with spinal cord compression, the primary objective is to take pressure off the cord, which can sometimes be accomplished with closed reduction and cervical traction. In hospitals without spine surgery capabilities or resource-poor settings where emergent surgery is not possible, traction can open up the spinal canal just as effectively as an open, direct surgical decompression. In most cases, surgery is still needed after successful closed reduction for stabilization reasons. Although thoracic and lumbar fractures do not typically respond to traction, patients with cervical spine subluxation through perched facets may benefit from closed reduction techniques. However, there are also some important contraindications, as traction is not safe in everyone and can also cause or worsen an SCI, such as more proximal fractures, AS, diffuse idiopathic skeletal hyperostosis (DISH), fracture patterns with retropulsed bone, and the presence of a herniated disc. Consultation with a spine surgeon is necessary to decide if traction is safe. Importantly, the patient must be awake to comply with examinations to closely monitor any new symptoms or neurologic deficits.

Traction involves employing longitudinal forces using either skull tongs or a halo headpiece cranially to reduce a fracture or perched/locked facets. Initially, a force of 5 to 15 pounds is applied, and this force is gradually increased in 5-pound increments, with lateral radiographs taken after each increment. For dislocations located more toward the upper part of the spine, less force is used, typically around 3 to 5 pounds per vertebral level. After weight is added, the patient is assessed for a complete neurologic examination to ensure no deterioration. After each weight is incrementally added, patients should get an x-ray and serial examinations until the limit is reached. Additionally, the administration of a muscle relaxant, analgesia, and/or sedation may facilitate the reduction process. An attentive neurologic examination is the gold standard for monitoring any impediment on the spinal cord. Once reduction is achieved, weight can be decreased to maintain the reduction.

Time to Surgery and Recovery

Timely access to decompressive surgery and early rehabilitation has suggested improvement in patient outcomes. The Surgical Timing in Acute Spinal Cord Injury Study found that performing decompressive surgery within the first 24 hours after SCI was associated with improved neurologic recovery, defined as achieving at least a two-grade advancement on the ASIA scale at 6-month follow-up.[37] Whether patients have an SCI or fracture with no damage to the SCI, stabilizing unstable fractures urgently is critical to continuing their ongoing care after trauma. Although important differences exist between high- and low-income countries with regard to available resources to provide timely intervention,[38] delays in surgical intervention can give rise to various nonneurologic complications associated with immobilization, such as pressure ulcers, deep venous thrombosis, pulmonary embolism, and pneumonia.

Although some studies have not witnessed any improvement in ASIA A patients after surgical treatment, recent data show that after at least 6-months of postoperative follow-up, as many as 20% of patients tend to have gradual neurologic recovery to a less severe ASIA grade.[39] Given prior studies showing the potential for improvement in select ASIA A patients, even patients with complete SCI may be taken to the operating room urgently at our center. Though this may not be necessary for all forms of SCI, it is worth a discussion between the trauma team and the spine surgeons.

Role of Steroids in Spinal Cord Injury

Despite some of the older randomized control trials indicating benefit,[40] the use of steroids in traumatic SCI has largely fallen out of favor and phased out of practice. The risks of high-dose glucocorticoid therapy, such as pneumonia, sepsis, gastrointestinal bleeding, wound infection, and diabetic ketoacidosis, are felt to outweigh its benefit in the injured patient.

Pediatric Spinal Cord Injury

Just as in adults, SCI in pediatric patients requires timely intervention, with some subtle differences. These injuries can occur at various levels along the spine, with the cervical spine being the most prone to injury (55%), followed by the thoracic spine (15%), the thoracolumbar junction (15%), and the lumbosacral region (15%). In adults, the most common cause of SCI is traumatic injuries, whereas in children, nontraumatic causes are more common. The most common nontraumatic causes of pediatric SCIs include congenital anomalies, spinal cord tumors, infections, and vascular malformations. The primary causes of traumatic SCI in children are diverse, with blunt trauma being the most common etiology related to motor vehicle accidents, falls, and sports-related injuries.

Distinct anatomy differentiates children's from adults' spines because children's vertebrae are incompletely ossified and their ligaments are firmly attached to articular bone surfaces that are more horizontal than in adults. In particular, younger children may have incomplete ossification of the odontoid process extending from the C2 level, along with a relatively large head and weaker neck muscles, which increases the risk of spinal instability compared with adults. This unique anatomic feature increases risk of SCI, without a fracture or radiographic abnormality in children under 8 years of age, as spinal elements may shift rather than break when subjected to force. A high index of suspicion is needed, and in the setting of a high-energy mechanism without fracture, close inspection of soft tissues for prevertebral edema in the cervical spine on CT imaging can trigger an MRI. A lower threshold for MRI in kids is advised to avoid missing unstable ligamentous injuries.

Traumatic Spinal Emergencies

Craniocervical Junction, C1, and C2 Injuries

Atlantooccipital dissociation (AOD) results from disruption of the craniocervical junction from ligamentous injury. These injuries are twice as common in pediatrics compared with adults, likely owing to higher cranium-to-body ratio and increased ligamentous laxity.[41] Clinical symptoms range from minimal neurologic deficit, given the spinal canal is often wide at the craniocervical junction, to severe upper cervical cord or brainstem damage from stretch injury to the neural elements. The Traynelis classification for AOD categorizes injuries based on the occipital condyle position in relation to atlas, distinguishing between three types: type I denotes anterior displacement, type II signifies distraction or inferior displacement, and type III represents posterior displacement.[42] Type II is the most dangerous, as the spinal cord does not tolerate stretch well.

Several radiographic methodologies can be used to diagnose AOD, with CT scan measurements having higher sensitivity and specificity compared with plain radiographs. One CT measurement assesses the occipital condyle to C1 distance, which should be 1 to 2 mm in adults (Fig. 41.7).[43] This distance is measured on each side, and if it is >2 mm or if any asymmetry exists, an MRI should be obtained. Other measurements include a basiondental interval (BDI), atlantooccipital interval, and the Powers ratio. Other imaging findings like craniocervical subarachnoid hemorrhage may be a marker of concomitant craniocervical junction instability.

Initial management for a patient in which AOD is suspected is immediate immobilization of the neck with halo or sandbags. AOD is a hard contraindication for traction. Surgical treatment with occipitocervical fusion is indicated. An example of AOD is illustrated in Fig. 41.8.

Occipital condyle fractures are often diagnosed on CT and are rarely surgical in isolation. Type I occurs from axial loading and results in comminuted fractures, type II is an extension of linear basilar skull fractures, and type III is an avulsion fracture of condyle fragment resulting from traction during rotation or lateral bending mechanisms. Almost all of these fractures can be managed in rigid cervical collar and radiographic follow-up in the absence of other cervical fractures.[44]

C1 fractures, or atlas fractures, were described by Sir Geoffrey Jefferson in 1920 and most commonly occur from axial loading resulting in fractures through the C1 arches, which are the thinnest part of the C1 vertebrae. Type I Jefferson fractures involve the posterior arch alone, type II fractures involve the anterior arch alone, type III fractures involve both the anterior and posterior arch, and type IV fractures involve the lateral mass. Clinical findings can include neck pain and associated vertebral artery dissections; however, neurologic deficits are rare with isolated C1 fractures because of the large diameter of the canal at this level. Stability at this level is primarily provided by ligaments, and therefore, integrity of the transverse ligament on MRI is the most important determinant of stability in C1 fractures and suitability for rigid cervical collar and follow-up. In some cases where the C1 lateral mass is fractured, if not stabilized, a cock-robin rotational deformity can ensue, where the lateral mass collapses on one side and the occipital condyle rests on the superior facet of C2. These patients may be treated with C1 open reduction and internal fixation (ORIF). Additionally, C1/2 ligamentous injuries can also present, with or without fractures of C1. A widened C1/2 joint distance can be seen, along with a widened atlantodental interval (ADI) of >3 mm.

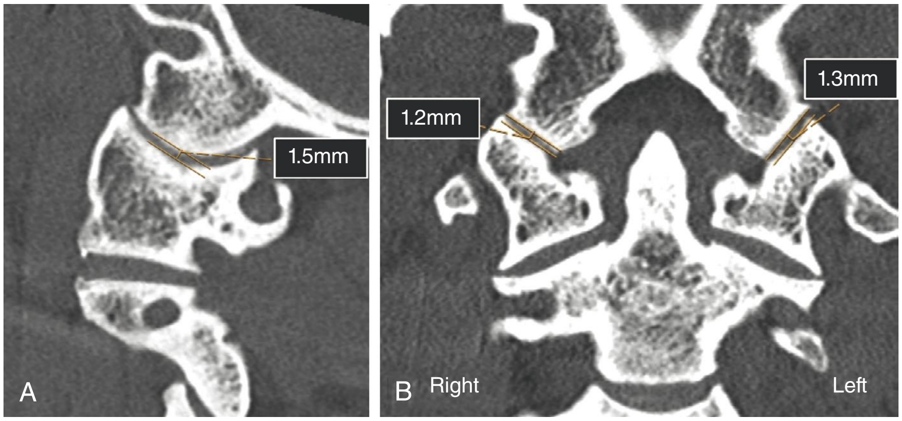

FIGURE 41.7 Example of normal occipital condyle to C1 distance <2 mm as measured on sagittal (A) and coronal (B) computed tomography scan.

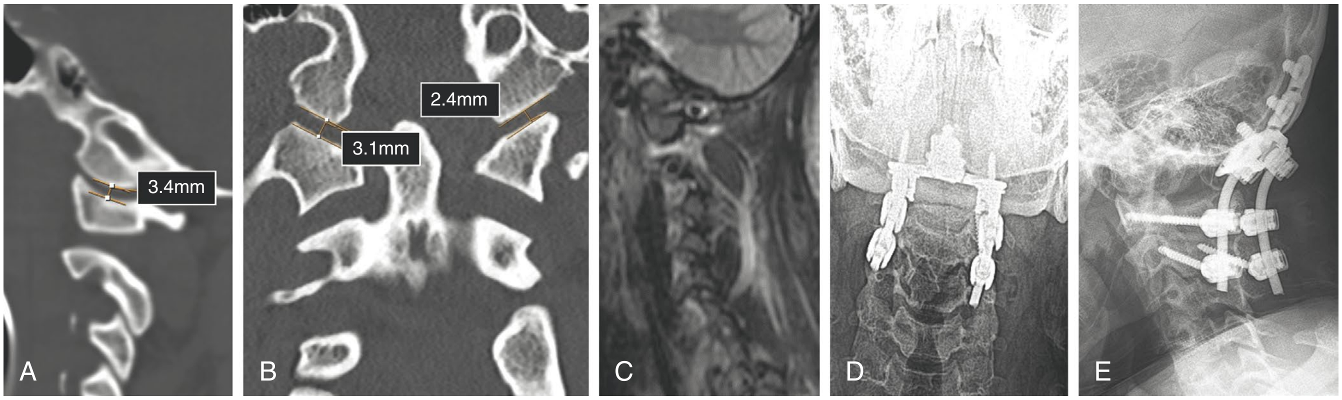

FIGURE 41.8 (A–E) Atlantooccipital dissociation on sagittal (A) and coronal (B) seen on computed tomography scan and hyperintensity within the C1–C2 facet seen on parasagittal magnetic resonance imaging (C). The patient underwent occiput-C2 fusion, seen on postoperative anteroposterior (D) and lateral x-ray (E).

C2 fractures, or axis fractures, can be classified as hangman's fractures, odontoid fractures, or a combination of both. As evident by the name, hangman's fractures occur from hyperextension and axial loading resulting in bilateral fracture though the pars interarticularis of C2. The majority of hangman's fractures can be managed with rigid cervical collar or halo immobilization. Levine and Edwards classification and the Effendi classification are commonly used to classify C2 fractures. An MRI should be obtained in cases of anterior subluxation of C2 on C3 >3 mm or severe C2 on C3 angulation, which can be a surrogate for C2–C3 disc and posterior longitudinal ligament disruption. Overall, spondylolisthesis of C2 on C3 of >6 mm, severe angulation of C2 flexed forward on top of C3 of more than 12 degrees, and damage to the C2/3 disc may warrant surgical stabilization. Odontoid fractures comprise 10% to 15% of all cervical spine fractures, and flexion is the most common mechanism of injury.[45] The Anderson and D'Alonzo classification system is the most widely used and best applied using coronal CT. Type I fractures involve the tip of the odontoid resulting from traction on the alar ligament, type II fractures involve the base of the odontoid, and type III fractures extend through the vertebral body. There is level II evidence that type II odontoid fractures in adults >50 years of age should be considered for surgical stabilization and fusion given higher rates of nonunion. The reason for higher nonunion rates in type II fractures is that the osseous dens has limited cancellous bone and blood supply, making healing a challenge. Nondisplaced type I to III odontoid fractures are initially managed with rigid cervical collar and immobilization. Surgical fixation is typically considered for dens displacement >5 mm, comminuted fractures, or failure to achieve alignment with external immobilization. Miscellaneous C2 fractures such as those involving the spinous process, lamina, facets, and lateral mass may be treated with rigid cervical immobilization with cervical collar or halo. Examples of hangman's and dens fracture are presented in Fig. 41.9.

Overall, many fractures of the occipital-C2 region are not emergencies and can be treated with cervical collars. However, the ones that require immediate attention are AOD, C1/2 instability, and certain hangman's or odontoid fractures. Any AOD finding, hangman's fracture that meets operative criteria as mentioned earlier, and severely displaced type II odontoid fractures are the ones to be most concerned about.

Cervical Teardrop Fractures

Teardrop fractures are flexion/compression injuries to the cervical spine and often lead to retropulsion, canal compromise, and SCI. Hyperflexion injuries can also result in fracture of the anterior inferior edge of the vertebral body, which is termed a *teardrop fracture.* Ultimately, MRI is necessary to assess the integrity of the disc and posterior ligaments to differentiate teardrop fractures

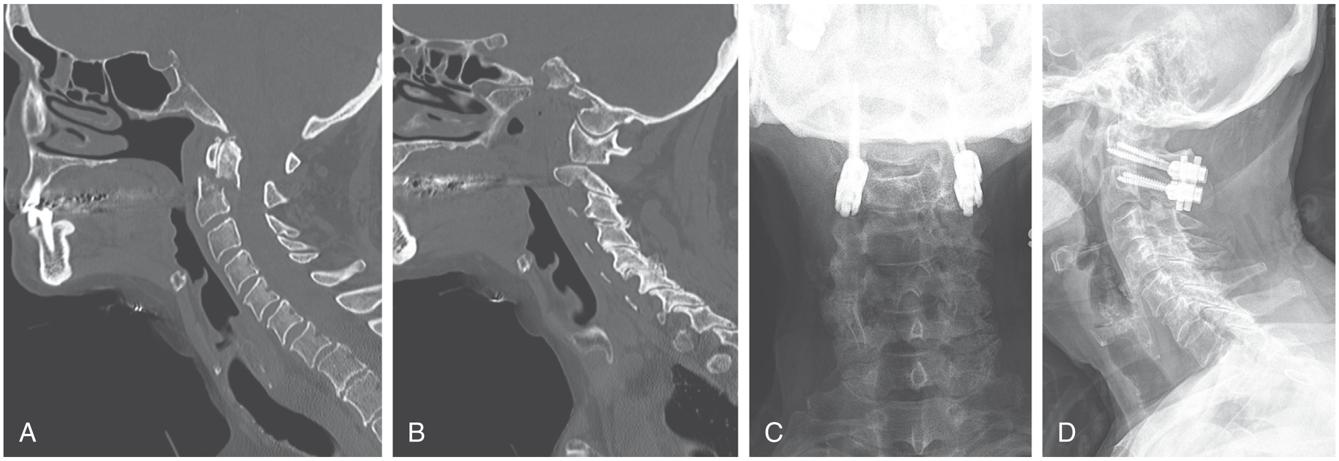

FIGURE 41.9 (A–D) Posteriorly displaced dens fracture (A) and hangman's fracture (B) on sagittal computed tomography scan. Patient underwent C1–C2 posterior fusion, as seen on postoperative anteroposterior (C) and lateral (D) x-ray.

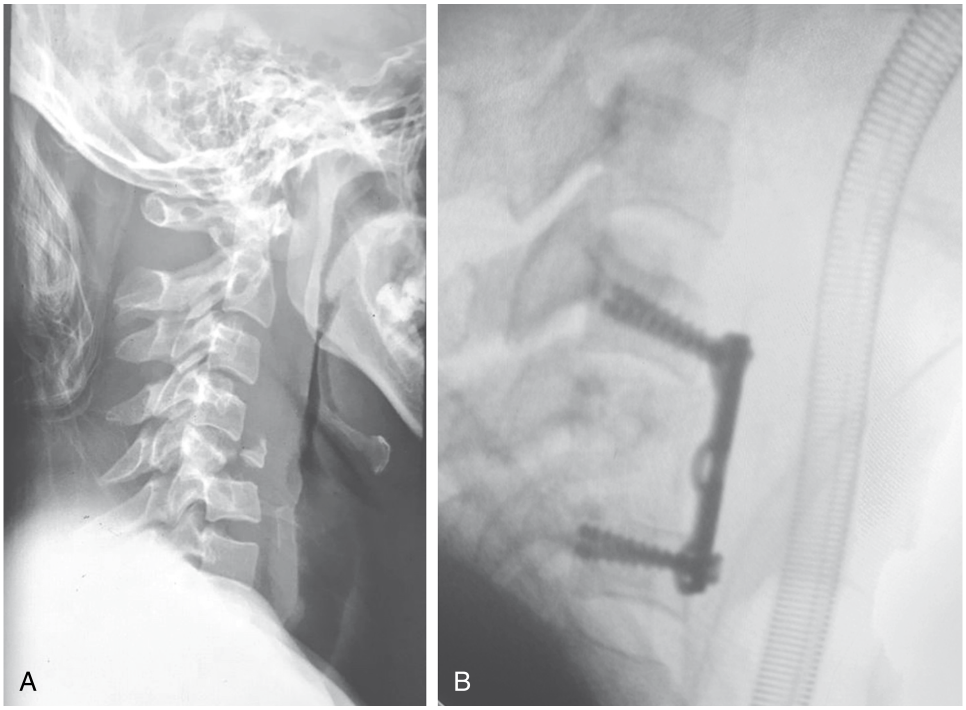

FIGURE 41.10 Teardrop fracture dislocation on lateral x-ray (A) in a resource-poor, low- to middle-income country. Although this fracture is usually treated by an anteroposterior approach, only anterior cervical corpectomy and fusion were performed using iliac crest autograft, as seen on postoperative lateral x-ray (B).

from spine avulsion fractures, the latter of which can be treated with rigid collar and repeat radiographs. Importantly, a teardrop fracture must be differentiated from an anterior osteophyte fracture. The former is a highly unstable injury, whereas an anterior osteophyte fracture is minor and only needs a collar. An example of a teardrop fracture is presented in Fig. 41.10.

Perched or Locked Cervical Facets

Severe flexion injuries can also result in locked, or “jumped,” facets, which involves disruption of the facet capsule. These injuries can best be classified in two ways. First, the injury is assessed to be unilateral or bilateral. Unilateral perched/locked/fractured facets usually result in an isolated radiculopathy, whereas bilateral perched/locked/fractured facets can often lead to SCI given the canal stenosis. The second way to evaluate the injury is if the facet is perched, locked, or fractured, which often occurs in older individuals with degeneration (Figs. 41.11 and 41.12). At our center, some combination of the three mechanisms is seen, often with the superior articular process being fractured. In cases where facets are not completely locked but have had significant ligamentous disruption resulting in distraction, the term used is *perched facets.* Typically, unilateral locked facets result from flexion and rotation injury, whereas bilateral locked facets typically result from hyperflexion only, with simultaneous disruption of the posterior ligamentous complex, and may result in SCI or nerve root deficits. Closed reduction with traction is employed for closed reduction of locked facets, which also opens up the spinal canal. After closed reduction, operative stabilization is often required.

Central Cord Syndrome

Central cord syndrome was originally described by Schneider and colleagues in 1954 and is the most common type of incomplete SCI. Central cord syndrome is most commonly seen in the adult trauma population after acute hyperextension injury in the setting of preexisting spinal stenosis from bony hypertrophy, redundant ligamentum flavum, or superimposed on congenital spinal stenosis. Injury can also be associated with cervical fracture or dislocation, acute traumatic disc herniation, or listhesis of one vertebra on another. Long tract cervical fibers passing through the cervical spinal cord are more medial and in the centermost vascular watershed zone, rendering them more susceptible to injury. Therefore, patients classically present with upper extremity weakness greater than lower extremity with varying degrees of sensory disturbances. Severe hyperesthesia, where patients are extremely sensitive to touch (allodynia and hyperalgesia) is common. MRI can detect T2 changes that may show spinal cord edema acutely. Initial management as previously described is recommended, and if there is ongoing cord compression, emergent surgery is needed. If the cord bruising is seen without significant compression, these patients can be treated without surgery.[46]

Thoracic/Lumbar Injuries and Burst Fractures

The Denis three-column model of the spine helps identify unstable thoracolumbar fractures with good predictive value. Minor injuries involve only part of a column and do not lead to acute instability and include spinous process fractures, transverse process fractures, pars fractures, and isolated laminar fractures. These minor injuries typically do not require intervention and may not require spine surgery consultation given local practice patterns and institutional protocols. However, thoracic/lumbar fractures in the setting of underlying AS and DISH may be highly unstable and warrant immediate immobilization and surgical evaluation. The thoracolumbar injury classification and severity score (TLICS) is a helpful tool for triaging when surgical intervention may be warranted and comprises three categories that include the morphology of injury (compression fracture, burst fracture,

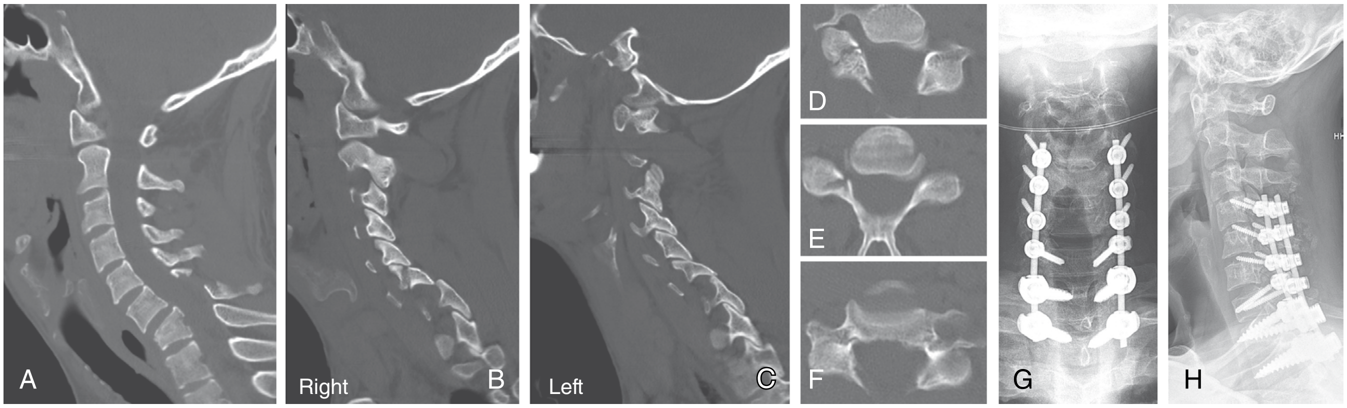

FIGURE 41.11 (A–H) C6 fracture dislocation on sagittal computed tomography (CT) (A), with right-sided jumped facet on right parasagittal CT (B), perched facet on left parasagittal CT (C), and right lateral mass fractures on axial CT scan (D–F). Patient underwent C4–T2 posterior fusion with restoration of normal alignment, as seen on postoperative anteroposterior (G) and lateral (H) x-ray.

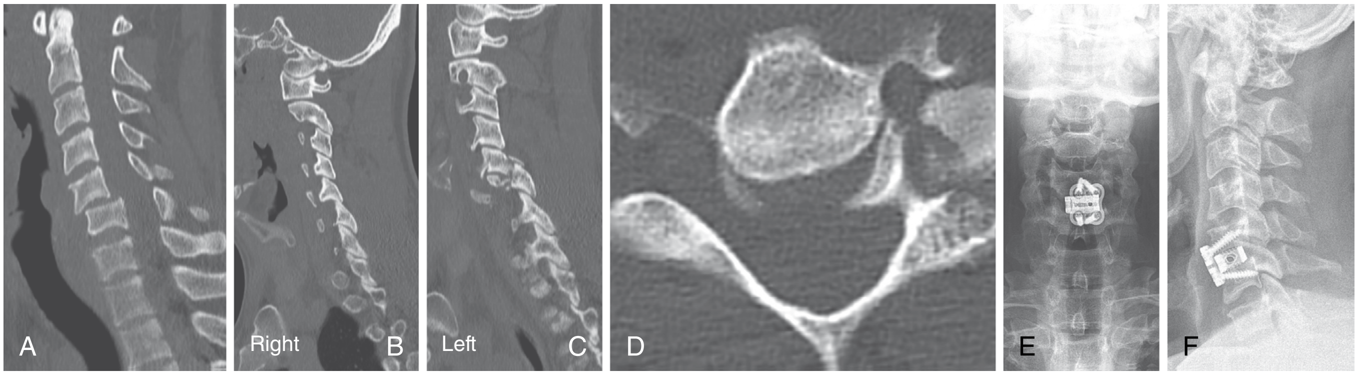

FIGURE 41.12 (A–F) C5–C6 fracture dislocation (A), with right normal alignment (B), left jumped facet on sagittal computed tomography (CT) (C), and left lateral mass fracture on axial CT (D). Patient underwent C5–C6 anterior cervical discectomy and fusion, as seen on postoperative anteroposterior (E) and lateral (F) x-ray.

distraction injury, and translational/rotational injury), neurologic status (intact, root injury, complete SCI, incomplete SCI, and cauda equina syndrome [CES]), and posterior ligamentous disruption. A TLICS of ≤3 is usually managed nonoperatively, whereas TLICS >4 is a candidate for surgery.[47]

Burst fractures typically occur because of axial loading accompanied by a bending moment resulting in an implosion of a vertebra, often causing a failure of the anterior and middle vertebral columns. Although conservative treatment can be used with bracing, close follow-up is needed to make sure the fracture is not progressing into more collapse or more kyphosis. Surgical intervention is often indicated if there is observable evidence of increasing angular deformity and the presence of spinal cord or cauda equina compression. Individuals exhibiting more than 30 degrees of angulation, greater than a 50% loss of vertebral body height, and neurologic symptoms should be considered candidates for surgical stabilization. An example of a burst fracture is illustrated in Fig. 41.13.

Chance Fractures and Flexion-Extension Injuries

Flexion-extension injuries encompass a broader range of spinal injuries resulting from sudden forward and backward movements of the spine, often in the midthoracic area where seatbelts are worn. A severe type of flexion-extension injury is represented by chance fracture, an unstable type of spine fracture. It is characterized by a horizontal break that spans from the posterior to the anterior aspect of the spinal column, traversing the spinous process, pedicles, and vertebral body.[48] Identifying chance fractures during a clinical examination can be challenging because patients seldom exhibit neurologic deficits. As stated, a seatbelt sign is a common finding on the physical examination, and accompanying intraabdominal injuries can be present in as high as 50% of cases, such as bowel or bladder rupture.[48] Current literature predominantly supports surgical treatment given the inherently unstable nature of this fracture and the disruption of ligaments. Examples of a chance fracture and flexion-extension injury are illustrated in Fig. 41.14.

Fracture Dislocation

Dislocations of the thoracic and lumbar vertebrae typically occur as a consequence of exceptionally high-energy trauma.[49] They result from the simultaneous application of multidirectional forces, combining both distracting and compressive elements across different spinal components. Consequently, these forces lead to the development of translational and rotational instability within the spinal column, often accompanied by associated fractures. Because of the instability resulting from posterior facet dislocation, treatment is often surgical and includes an open reduction with posterior fusion.[49] An example of fracture dislocation is illustrated in Fig. 41.15.

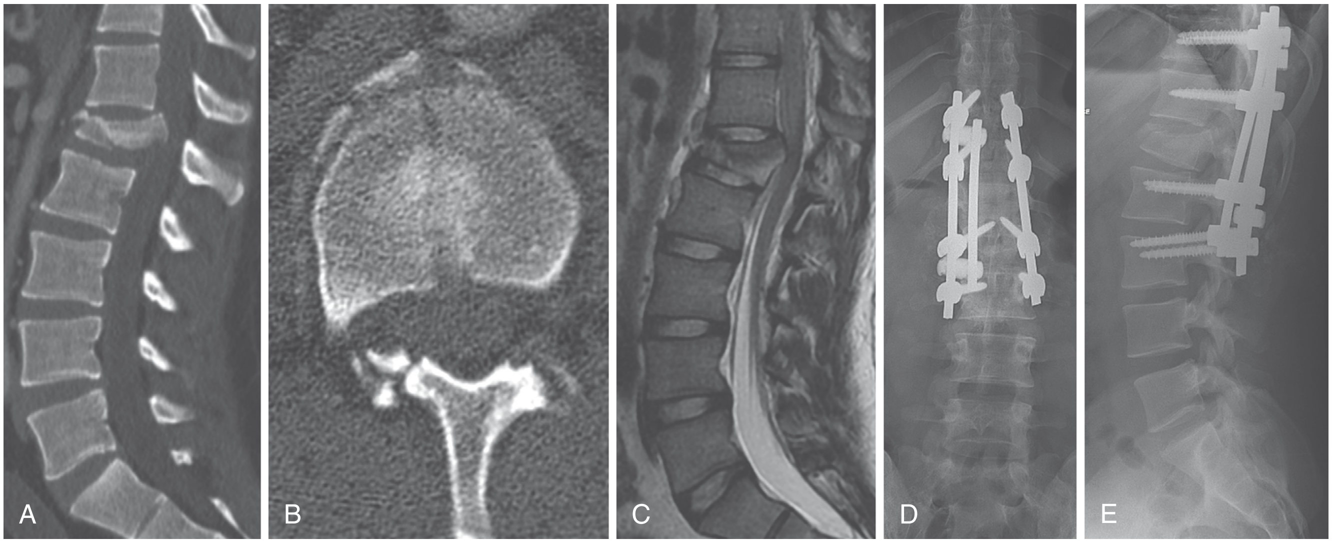

FIGURE 41.13 (A–E) Burst fracture of L1 on sagittal (A) and axial (B) seen on computed tomography scan. Magnetic resonance imaging showed canal stenosis and thecal sac compression (C). The patient underwent L1 laminectomy with T11–L3 posterior fusion, as seen on postoperative anteroposterior (D) and lateral (E) x-ray.

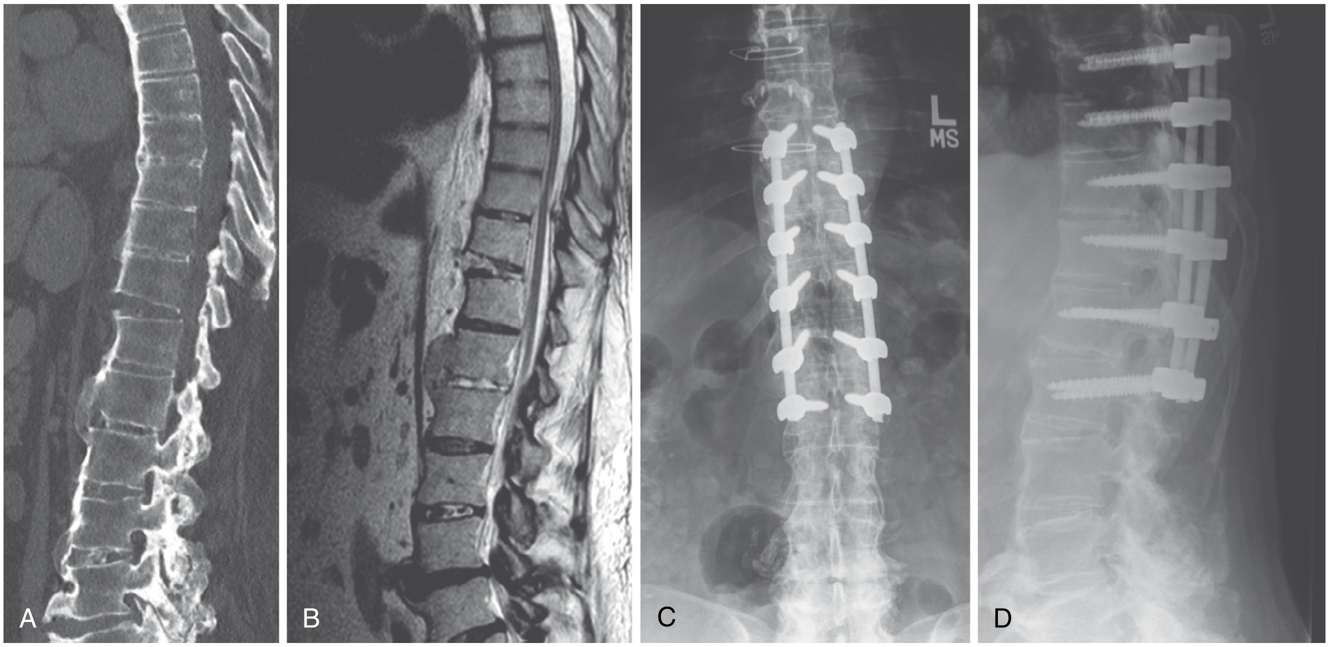

FIGURE 41.14 (A–D) Three-column T11–T12 extension injury with widening of the disc space anteriorly and extension of fracture through the posterior elements of T11 as shown on sagittal computed tomography scan (A) and T2 magnetic resonance imaging (B). The patient underwent T9–L2 posterior fusion, as seen on postoperative anteroposterior (C) and lateral (D) x-rays.

Nontraumatic Spinal Emergencies

Spinal emergencies can occur in the nontraumatic setting as well. In this section, we cover CES, spinal tumors, spinal vascular malformations, and spine infections.

Cauda Equina Syndrome

Cauda equina comes from Latin for *horse tail* because of the appearance of the nerves dangling within the thecal sac. When these nerves are compressed, a classic series of symptoms termed *cauda equina syndrome* can be seen, thought to be the result of a combination of mechanical and ischemic changes. A classic trio of symptoms includes bilateral lower extremity weakness and decreased sensation, loss of bowel/bladder function, and saddle anesthesia. It is rare to see all three symptoms at once, whereas in reality, CES presents incompletely with some symptoms, such as urinary hesitancy, groin numbness, and slight pain/weakness.

In the setting of an acute disc rupture, approximately 1% to 3% of patients will develop CES, and 45% of cauda equina cases are attributable to a lumbar disc herniation. When the cause of CES is a disc rupture, these patients are often younger with large, well-hydrated discs that can herniate, compared with an older population that suffers from lumbar stenosis. Other etiologies

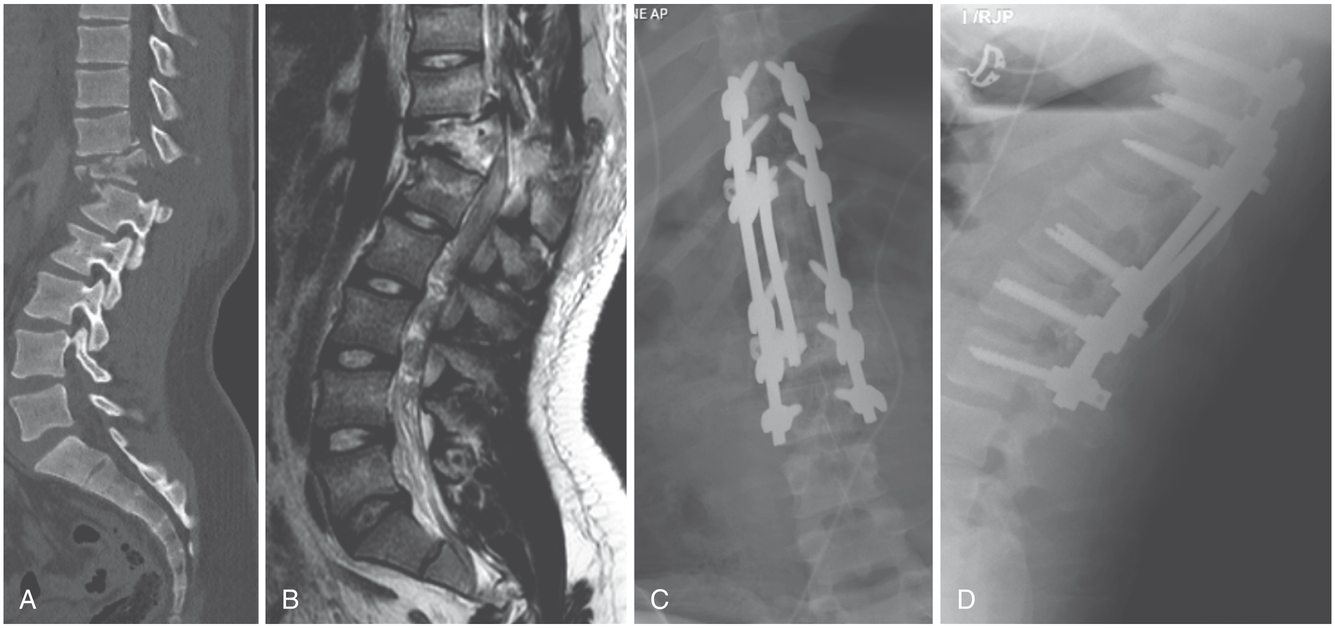

FIGURE 41.15 (A–D) Sagittal computed tomography scan showing fracture dislocation of T12 vertebra (A). Magnetic resonance imaging showed severe spinal cord compression (B). The patient underwent T9–L3 posterior fusion with a significant improvement of alignment, as seen on postoperative anteroposterior (C) and lateral (D) x-ray.

that may lead to CES include infection, symptomatic stenosis, hematoma, trauma, tumor, vascular abnormalities, or iatrogenic causes.

When evaluating a patient with concern for CES, a thorough and accurate physical examination, including a digital rectal examination, is essential. Bowel and bladder dysfunction are mainly due to disruption of the parasympathetic and sympathetic nerve function. Bilateral lower extremity weakness and saddle anesthesia also originate from compression of their corresponding nerves. Patients may also have decreased reflexes, and symptoms often start slowly but reach a critical threshold where patients become acutely symptomatic or their symptoms become progressive enough to warrant treatment. It is important to assess reflexes and muscle strength in the lower extremities, conduct a digital rectal examination to assess anal tone, and evaluate for any numbness in the perineal region. If a patient presents with these symptoms, an emergent MRI of the lumbar spine is of the utmost importance as this will drive surgical decision-making. If the patient is unable to undergo MRI because of contraindication, an emergent CT myelogram of the thoracic or lumbar spine should be obtained. To assess bladder function, an ultrasound bladder scan or catheterization should be performed to obtain a postvoid residual value. Patients may or may not have pain related to their CES depending on the acuity and severity of compression. If the MRI or CT myelogram shows evidence of compression of the cauda equina, spine surgery should be contacted immediately to determine need for emergent decompression.

Surgical management includes decompression of the cauda equina by laminectomy as well as removal of the offending lesion (e.g., disc herniation, infection). Although the quality of literature regarding timing of decompression in CES is poor, the recommendation is to take the patient to the operating room within the first 48 hours of symptom onset. Given the often unclear timeline of symptoms, emergent decompression within hours is often pursued. Studies suggest that as many as 85% of patients will return to their previous baseline, including bowel/bladder function and motor function, within 1 year after decompression. Reiterating the importance of timing, despite loose recommendations of timing, these injuries are best dealt with immediately, within hours of presentation.

Although CES is uncommon compared with many other spinal pathologies that are seen, incorrect evaluation, diagnosis, and management can result in severe neurologic impairment and have a devastating impact on a patient's quality of life.

Spinal Tumors

Metastatic spinal lesions are the most common spinal tumors and are seen in more than 20,000 people per year in the United States. Up to 14% of all cancer patients have metastatic spinal involvement. In addition, primary spinal tumors (PSTs) affect 2.5 to 8.5 people per 100,000 per year. Metastatic tumors most commonly cause cord compression and myelopathy, leading to an indolent onset of pain, weakness, numbness, balance deficits, urinary issues, hyperreflexia, and, in severe cases, weakness.

A full discussion of spinal tumor management is outside the scope of this chapter; however, we mention several key aspects of management. As noted earlier, a detailed neurologic examination is required. Additionally, imaging of the neural elements, most often an MRI with and without contrast, is needed, in addition to CT of the chest, abdomen, and pelvis to assess for bone quality and any other primary tumor source. Additionally, lesions that affect bony or ligamentous components of the spine can lead to inherent instability of the spine, which increases risk of neurologic deficit caused by secondary injury of neural elements. A score that is used to assess stability of the spine is the Spinal Instability in Neoplastic disease Score (SINS) (Table 41.6).[50] The SINS was created for nonspine surgeons, such as oncologists and radiologists, to recognize unstable fractures, and using it can be an important tool in knowing who needs urgent/emergent evaluation. A SINS of 0 to 6 receives a

TABLE 41.6 **Spinal Instability Neoplastic Score (SINS)**

ELEMENTS OF SINS	SCORE
Location	
Junctional (occiput–C2, C7–T2, T11–L1, L5–S1)	3
Mobile spine (C3–C6, L2–L4)	2

CV, Costovertebral.

"stable" designation, 7 to 12 receives an intermediate designation, and 13 to 18 is designated "unstable." Surgical consultation is recommended for patients with a SINS score of 7 or higher, which serves as a valuable tool for both surgeons and nonsurgeons to assess stability of the spine. If an unstable lesion is encountered, keep the patient in strict spine precautions until a spine surgeon can assess the patient.

From a surgical perspective, there are three main reasons to perform surgery: curative resection of a primary spinal malignancy, relieve cord compression and neurologic deficit, or stabilize an unstable spine. In patients presenting with neurologic deficits secondary to compression of neural elements, the goal of surgery is to decompress those elements and maintain normal function or allow the patient the best opportunity for return of function. In patients with spinal cord compression from spinal metastases, studies have shown that decompressing the spinal cord improves ability to walk, among other outcomes.[50] Another goal of decompressing the spinal cord allows for the creation of a margin to optimize radiosurgery planning to allow for higher doses to the entire lesion while protecting the spinal cord, known as *separation surgery*.

Intradural spinal tumors, both extramedullary and intramedullary tumors, account for less than 5% of all CNS tumors. The most common presentation is nocturnal back and leg pain, when endogenous steroids have worn off, and the presence of neurologic deficits becomes apparent. Examples of intradural extramedullary tumors include meningiomas, nerve sheath tumors, and schwannomas. Intramedullary tumors are most commonly gliomas, including ependymomas (most common in adults), astrocytomas (most common in pediatric populations), and oligodendrogliomas. When first encountered in an emergency setting with neurologic deficit, after consultation with a neurosurgeon, optimizing cord perfusion and starting steroids is the best initial management. Treatment for these lesions is typically surgical resection with consideration of radiation and chemotherapy as indicated.

Vascular Malformations and Spine Infections

Spinal vascular malformations are the result of abnormal development of blood vessels of the spine and include neoplastic lesions such as hemangioblastomas and cavernous malformations as well as benign lesions such as dural arteriovenous fistulas (dAVFs) and AVMs.

Patients will typically present in an acute manner, if there was hemorrhage, or in a chronic fashion, often secondary to venous hypertension, cord ischemia, or mass effect. Patients endorse symptoms of myelopathy including lower extremity weakness, decreased sensation, and bowel or bladder incontinence. A vascular etiology should also be suspected if the patient has a series of acute neurologic deficits after each other, consistent with a stepwise decline, which can often be seen because of episodic venous congestion and hypertension leading to hypoperfusion.

After presentation, lesions are most frequently diagnosed on MRI or magnetic resonance angiography (MRA) of the spine. Scans typically show T2 hyperintensity secondary to surrounding edema or venous congestion at the level of the lesion. CT angiography (CTA) is feasible as a diagnostic modality when MRI is not available. The gold standard of evaluation for these lesions is spinal angiography, which not only allows for characterization of the lesion itself but also an assessment of the dynamic inflow and outflow of blood within the lesion.

Treatment options include use of endovascular technology to occlude the inflow and/or outflow of the lesion, thus decreasing or obliterating the lesion. In cases planned for open surgical resection, preoperative embolization can minimize blood loss and simplify the procedure. In select patients, radiosurgical treatment may be used, but the data regarding this intervention are minimal and of poor quality.

Infection

Spine infections account for 2% to 7% of all musculoskeletal infections. The infection may involve the vertebral body or disc or create an abscess within the spinal canal. Multiple locations are often seen at the time of diagnosis as there is often a nonspecific and indolent nature to the presentation. Patients present with systemic infectious symptoms as well as back pain or neurologic deficit. Neurologic deficits are secondary to compression from an epidural abscess or a pathologic fracture.

Workup for these patients includes laboratory studies (complete blood count and basic metabolic panel, erythrocyte sedimentation rate, C-reactive protein, and blood cultures) to assess for signs of infection. Blood cultures and urine cultures should be obtained before initiation of any antibiotics to allow for possible identification of the causative microbe.

Involvement of the spine is often found by CT scan, which will show evidence of bony changes secondary to chronic inflammatory responses and osteomyelitis; however, CT scans may be negative in the setting of an isolated abscess without osteomyelitis. These patients usually undergo an MRI, which allows for further classification of the infection regarding surrounding tissues as well as the spinal canal. The most common causative agents are bacterial and fungal infections. *Staphylococcus aureus* accounts for as much as 80% of these infections. *Escherichia coli* is another common bacterium causing these infections.

In patients with no sign of instability, evidence of neurologic deficits, or spinal cord compression, a CT-guided biopsy is recommended, if safe, to narrow antibiotic coverage. If the patient presents with acute-onset neurologic deficits and is found to have a compressive epidural abscess, emergent surgical intervention is warranted to decompress the neurologic structures and optimize the patient's overall recovery. In these cases, no CT-guided biopsy is needed as intraoperative cultures can be obtained for diagnostic purposes.

Once a sample is obtained, the patient is started on broad-spectrum antibiotics until culture results finalize, including sensitivities, to allow for targeted antimicrobial therapy. Antibiotic regimen and course are guided by the causative agent. Appropriate management of this pathology typically requires a multidisciplinary team including infectious disease, interventional radiology, and spine surgery.

Summary of Spine Emergencies

Time plays a decisive role in managing traumatic SCI, and swift recognition by neurologic examination and imaging is the cornerstone to diagnosis and treatment. Furthermore, the importance of spinal cord perfusion and consideration of MAP goals on presentation is helpful in almost any type of SCI, particularly for the acute care surgeons who are the first to triage these injuries. Simply put, surgical treatment often comes in the form of decompressing compressed neural elements and stabilizing an unstable spinal column. The landscape of emergency spinal injury care is in a state of perpetual evolution, driven by dedicated researchers, healthcare professionals, and breakthrough technologic innovations.

  Injury Prevention and Advocacy

INTRODUCTION

Epidemiology

Trauma is the leading cause of mortality for children and young adults aged 1 to 19 years and the third leading cause of death for infants <1 year of age.[1] Blunt injury accounts for over 90% of pediatric injuries, with falls and motor vehicle crashes (MVCs) being the most common mechanisms of injury (MOIs). MOI varies substantially with the age of the child and depends on developmental abilities and exposure to potential harms. Nonaccidental trauma (NAT) must be habitually considered at all ages, particularly for ages <2 years. The most common causes of death from *unintentional* injury per age group are suffocation for children <1 year, drowning for children 1 to 4 years, and MVCs for children older than 5 years.[1] Among all children aged ≤19 years, there were 9.0 deaths per 100,000 children in 2019 from unintentional injury, exceeding all other causes of mortality in the pediatric population. Furthermore, fatality rates differ with geography and were higher in rural settings compared with urban settings (17.8 per 100,000 vs. 6.8 per 100,000). Despite overall improvements in mortality from unintentional injury, there has been a steady increase in the number of pediatric deaths from all types of firearm injury, including homicide, suicide, and unintentional shootings. As such, firearm injury is now the leading cause of mortality for all children.[2]

Pediatric Differences

The aphorism "a child is not a small adult" is particularly pertinent when discussing pediatric trauma because injured children are frequently treated at centers that primarily care for adults. It is easy to *inappropriately* extrapolate adult-based principles and management strategies to the child. Further, within the pediatric population, there is an enormous degree of heterogeneity.[3] Providers should be intimately familiar with anatomic and physiologic differences between age groups so that infants, young children, and adolescents can all be treated within the unique context of their physiologic and developmental stage. For example, securing a stable airway, obtaining intravenous access, and providing adequate resuscitation are very different for an infant than for an adolescent. Emotional, psychological, and social needs also differ significantly as children mature.

Despite this heterogeneity, several key tenets should remain front of mind during the trauma evaluation. First, the developing skeleton is relatively flexible and lacks the maturity of an adult skeleton. This, combined with the reduced body mass, leads to the potential for transmission of energy to internal organs. This may result in a greater degree of internal morbidity than would be suggested from the initial *external* examination, such as the development of pulmonary contusions in the absence of rib fractures or a bladder injury in the absence of a pelvic fracture. Second, children have an increased head size relative to their body, making them particularly vulnerable to head trauma. Finally, their increased surface area to mass ratio puts children at risk for hypothermia.

Prehospital Arrival

Early hospital notification allows the trauma resuscitation team to assemble in the emergency department (ED) with appropriate personal protective equipment donned, team roles assigned, and any prehospital information clearly communicated before arrival. Relevant consulting services (e.g., neurosurgery, orthopedics) can be notified in advance based on available information, and necessary equipment should be confirmed as available and properly functioning. The trauma resuscitation team will include, at a minimum, a senior team leader trained in Advanced Trauma Life Support (ATLS), a clinician responsible for the primary and secondary survey, a clinician assigned to the airway, an airway assistant or respiratory therapist, two nurses, a provider responsible for medication preparation and administration, and someone to document. Representatives from anesthesia, social work, child life, and pharmacy may also be included based on availability and the specific needs of the patient. Roles should be clearly assigned, and crowd and noise control maintained at all times.

RESUSCITATION

Primary Survey

The initial assessment of injured children mirrors that of adults, systematically addressing the "ABCDEs" using ATLS principles. However, despite similar processes, when caring for children there are unique characteristics that are important to recognize. To optimally care for injured children, providers should be familiar with the nuanced differences in anatomy, physiology, injury pattern, and psychosocial needs of injured children. Adding to this complexity of caring for children are variable size, maturity, and developmental stage. For example, the management of the neonatal airway is markedly different from that of the teenager. It is worth noting that even when an adolescent child nears physical maturity and looks "adult," their emotional, psychological, and social needs still require special attention. Regardless of age, development stage, or injury, the *primary goal of trauma resuscitation is to restore and maintain oxygen delivery, identify and manage injuries in order of greatest threat to life, and expeditiously provide appropriate disposition.*

Airway

Errors in airway management can be unforgiving and lead to preventable death.[4] Given their increased metabolic rate and decreased reserve, children have a nefarious ability to desaturate on pulse oximetry in seconds—with resultant hypoxia the most frequent cause of cardiac arrest. That being said, with thoughtful preparation and anticipation of potential pitfalls, airway complications can be avoided.

Rapid assessment of airway patency and ability to protect the airway can be accomplished by having the child phonate. A child that is speaking or crying clearly is one that has a patent airway. Hoarseness, stridor, or evidence of inhalation injury are all indicators that airway compromise may be imminent. Simultaneous with assessment of airway, the cervical spine should also be assessed to confirm cervical immobilization is *correctly* applied. Frequently the cervical collar is the wrong size, misapplied, or improvised.

Specifically related to the pediatric airway and anatomy, the child's large occiput can create relative neck flexion leading to obstruction. One solution is to place a blanket or roll under the upper back to help the neck maintain a neutral position. Other pertinent anatomic differences include a large tongue, small mouth, anteriorly displaced epiglottis, short trachea, and small diameter (which is most narrow at the level of the cricoid cartilage; Fig. 42.1). Regarding the shorter trachea, attention is needed to prevent inadvertent mainstem intubation or accidental tube dislodgement.

Despite these differences, the chin lift and jaw thrust are particularly good maneuvers to open the airway. Children can typically be maintained with these techniques and bag-valve-mask (BVM) ventilation for substantial periods while the appropriate medications, equipment, and personnel are being readied to perform intubation. The indications to intubate injured children typically mirror that of the adult trauma patient.

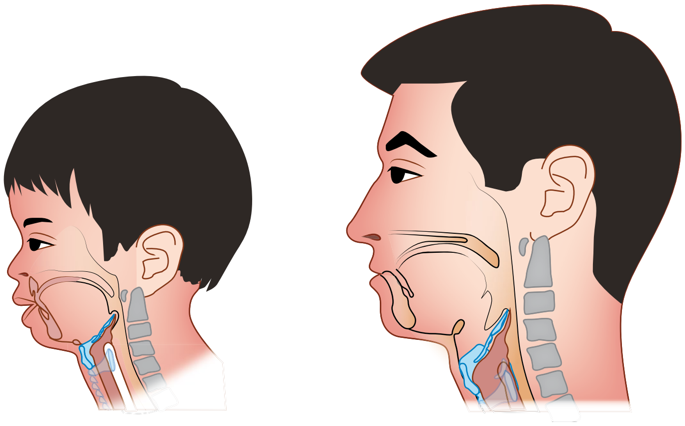

FIGURE 42.1 Differences in anatomy between the pediatric and adult airways.

Indications for endotracheal intubation in the pediatric trauma patient include:
- Airway obstruction
- Respiratory distress
- Poor respiratory effort
- Inability to protect airway
- Deteriorating mental status
- Glasgow Coma Scale (GCS) <8
- Penetrating neck trauma with possible airway compromise
- Suspicion for inhalation injury

Pediatric airway pearls:
- Infants typically will require a 3.0 to 3.5 uncuffed endotracheal tube (ETT).
- Older children can usually accommodate a cuffed ETT with size calculated as follows: (age in years/4) + 3.5.
- Alternatively, the size of ETT is roughly the diameter of the child's pinky finger or diameter of their nostril.
- Depth can by estimated by three times the ETT size.
- Size of oral airway can be estimated by the distance from central incisors to angle of mandible.
- Size of nasal airway is from nose to tragus.

Although video laryngoscopes (VLs) are becoming more widely available and can be helpful for visualization, in children with limited neck mobility, retrospective reviews have not shown that intubation using VL leads to a higher first-pass success rate.[5] Given a child's ability to rapidly decompensate, the most experienced provider should routinely be assigned to manage the airway. Yet even with the most experienced providers and teams, it is always important to have a backup plan. One scenario that can unravel the most seasoned team is the child who is able to be BVM ventilated before administration of rapid-sequence intubation (RSI) drugs but subsequently obstructs their airway after paralysis, resulting in a "can't intubate, can't ventilate" scenario. Having adjunctive measures immediately available, such as an oral airway or laryngeal mask airway (LMA) may be lifesaving. Caution is also warranted when administering RSI drugs in the setting of compensated hemorrhagic shock, where a child may have reduced sympathetic tone, and administration of RSI medications may precipitate cardiovascular collapse. If the patient needs to be managed in the operating room for hemorrhagic shock and the child still has an airway and can be oxygenated and ventilated, the operating room is frequently the safer place to obtain a definitive airway. In adults, not only does ED intubation not decrease time until definitive surgery, but it is also associated with postintubation, traumatic cardiopulmonary arrest.[6] Given that pediatric patients are even more prone than adults to rapid decompensation, the location where intubation is attempted should be thoughtfully considered. It is important that practitioners be familiar with difficult airway protocols and resources at their institution.

When an airway cannot be secured from above and a surgical airway is necessary, a surgical *cricothyroidotomy should typically be avoided in children less than 12 years*. In younger children the airway is more compressible and mobile; therefore, performing a cricothyroidotomy in these small airways may prove prohibitively difficult and may cause damage to the larynx. For younger children, percutaneous transtracheal needle insufflation is an option. In brief, a 14- or 16-gauge angiocatheter may be inserted into the trachea with a caudal trajectory, being cautious not to enter the backwall of the trachea. This is then attached to a 3-mL Luer-Lok syringe with the plunger removed. The open end of the syringe can then be attached to the hub of a 7.0 ETT and may be hooked up to high-flow oxygen (15–20 L/min). This may serve as a temporizing measure because hypoxia is the most time-sensitive physiologic determinate and hypercarbia is very well tolerated in children. Such measures can allow time for advanced airway techniques (e.g., use of fiberoptic equipment) or conversion to a formal tracheostomy for children requiring a surgical airway.

Breathing

Initial assessment of breathing is performed by inspection of the chest wall for evidence of trauma or asymmetry, auscultation bilaterally, palpating for crepitus or chest wall instability, and feeling for tracheal deviation. Respiratory distress may be indicated by grunting, nasal flaring, belly breathing, or use of accessory muscles. As assessment is ongoing, supplemental oxygen should be empirically administered and pulse oximetry monitored. When BVM ventilation is necessary, care should be taken to avoid overventilation. Typical tidal volumes range from 6 to 10 mL/kg for children, and appropriate respiratory rate will vary dependent on age. Use of BVM ventilation and the upset, crying child may both result in profound gastric distention from aerophagia, with resultant change in respiratory mechanics as the air-filled stomach pushes up on the diaphragm. Additionally, profound gastric distention may misdirect the naïve practitioner to the deduce that there is abdominal pathology (i.e., abdominal distention or rigidity, or gastric distention; see Fig. 42.4).

Breath sounds may be present bilaterally, despite significant unilateral pathology. Listening more laterally may help prevent confusing referred sounds from the contralateral chest. When breath sounds are unequal, the differential diagnosis of contusion, pneumothorax, hemothorax, or mainstem intubation should be considered. It is easy to advance the ETT into the mainstem bronchus (especially on right side), and this must be included in the differential when breath sounds are absent unilaterally in the intubated patient.

If life-threatening pathology is noted when examining the chest, just as when caring for adult trauma patients, intervention is warranted. Treatment of tension pneumothorax should be based on clinical suspicion, not radiographic confirmation. Inserting an angiocatheter into the pleural space, either in the midclavicular line at the second intercostal space or anterior axillary line at the fifth intercostal space, is an appropriate initial treatment. Alternatively, a chest tube may be placed if time permits. Although arbitrary, the indication for thoracotomy to manage massive hemothorax includes initial drainage of 20% of total blood volume or ongoing losses of $\sim$2 mL/kg/h. As with all pediatric resuscitation and management, this threshold is weight dependent, and a 3-month-old will reach this threshold at a much lower volume of blood loss compared with a 13-year-old. However, regardless of absolute outputs, the overall clinical picture should be the primary determinant of when to pursue operative intervention for hemothorax.

Circulation

When evaluating and managing circulation in pediatric trauma, goals include:

1. Control external bleeding
2. Recognize shock
3. Quickly obtain IV access
4. Initiate resuscitation

Although these goals appear simple enough, children can present unique challenges. The smaller the child, the smaller the circulating blood volume. The overall circulating blood volume in children is $\sim$70 cc/kg ($\sim$80 cc/kg for infants). Unlike adults in shock, children typically do not increase stroke volume in response to hypovolemia; rather, they are dependent on heart rate to maintain cardiac output along with a robust compensatory ability to increase vascular tone. Blood pressure is maintained by cardiac output (tachycardia) and increased vascular tone until late in hemorrhagic shock. In children, blood pressure may be preserved until loss of $>$45% of blood volume. Evidence that a child is in shock can be subtle, and an astute clinician will recognize clues in the level of consciousness, skin including capillary refill, heart rate, and blood pressure. Blood pressure has intentionally been listed last. Children may maintain their blood pressure right up until the point of cardiac collapse. Providers should be familiar with normal vital signs of different age groups (Table 42.1).

When significant external bleeding is identified, direct pressure is the preferred method of immediate control. Supplementary methods for control include pressure on the proximal arterial inflow or application of a tourniquet. If a tourniquet is not available, a blood pressure cuff can be effective, with inflation of the cuff above the arterial pressure and clamping of the tubing to keep it inflated. A tourniquet can be left in place roughly 2 hours with little risk of permanent ischemic injury. Continuous application for 6 hours or more will likely require amputation of the extremity.

If external hemorrhage is not present, assessment of circulation can begin with palpation of the central pulses, obtaining a peripheral blood pressure with an appropriately sized cuff, applying

TABLE 42.1 Normal Vital Signs of Different Age Groups

AGE	KG	RESPIRATORY RATE	HEART RATE	SYSTOLIC BLOOD PRESSURE (SBP)[a]
Preemie	1–3	<60	<180	>60
Infant (0–6 mo)	3–5	<60	<180	>60
Infant (6–12 mo)	7	<40	<160	>70
Toddler (1–3 yr)	10–15	<35	<150	>70
Preschool (3–6 yr)	15–20	<30	<140	>75
School age (6–12 yr)	20–40	<25	<120	>80
Adolescent (≥13 yr)	40–70	<20	<100	>90

[a] SBPf >70 + (2 × age in years).

electrocardiogram (ECG) leads, and obtaining venous access. If peripheral intravenous access is difficult, ultrasound guidance should be readily available. If that remains difficult, intraosseous (IO) access at the proximal tibia, distal femur, or humerus should be used. An injured extremity should not be used for IO access. Central venous access can be considered but can be challenging and time consuming in the small child. Proximal or distal saphenous vein cut-down is a useful technique as well, although infrequently necessary. IO access should be the first approach in the child in extremis without access.

Once IV access is obtained, children typically first receive a 20 mL/kg fluid bolus. If hemorrhagic shock is present, early transfusion of O-negative blood should be pursued with consideration of activation of the massive transfusion protocol. Principles of damage control resuscitation—avoiding excess crystalloid, balanced resuscitation, early hemorrhage control—should be applied to children as in adults. Excess crystalloid administration has prospectively been evaluated and found to be associated with worse outcome, supporting use of an early transfusion approach in the resuscitation of injured children.[7] Balanced transfusion should be pursued, although a rigorous 1:1:1 balanced transfusion ratio has less support in the pediatric literature than it has in adults.[8] Additionally, evidence is growing that use of low-titer whole blood may be beneficial in the resuscitation of children in hemorrhagic shock.[9] Although tranexamic acid (TXA) is a useful adjunct to address hyperfibrinolysis in adults, its use in children remains under investigation; however, it can be administered within 3 hours of injury. When used, TXA is first given as a loading dose of 15 mg/kg (max 1 g) and then infusion of 2 mg/kg/h for 8 hours.

Transfusion volumes:

- Packed red blood cells: 10 to 20 mL/kg
- Plasma: 20 mL/kg
- Cryoprecipitate: 1 unit/10 kg
- Platelets: 15 mL/kg

While resuscitation is pursued, the potential locations of blood loss should be assessed including the chest, abdomen, pelvis, extremities, and externally. Typically, the location of hemorrhage can be ascertained via the physical examination, chest x-ray (CXR), and pelvic x-ray. The role of focused assessment with sonography for trauma (FAST) is less defined in injured children than in adults. The hemodynamically unstable child with a tender or distended abdomen will still need to be taken to the operating room regardless of findings on FAST. Conversely, a stable patient with free fluid on FAST will still require CT of the abdomen/pelvis to define the injury. In the setting of multisystem blunt injury, FAST may be helpful, provided it can be obtained quickly, can be interpreted with appropriate skepticism, and does not interfere with more pressing maneuvers. Some centers have adopted "extended" FAST (eFAST) in which the pleural space is evaluated for pneumothorax and hemothorax.

Additional points worth emphasizing when discussing circulation include that the quiet child with tachycardia and cool extremities in the trauma bay should make the practitioner very anxious—this is the child at risk of imminent cardiovascular collapse. Although tachycardia is the most consistent indicator of shock, this is not specific. Fear, anxiety, and pain are also common causes of tachycardia in the injured child. Clinical experience is important to help interpret the subtle clues to determine why a child is tachycardic. Bradycardia should also raise the practitioner's anxiety, as this may also suggest impending cardiovascular collapse.

Disability

Traumatic brain injury (TBI) is the leading cause of morbidity and mortality in pediatric trauma. The relatively large size of the child's head compared with the rest of the body predisposes them to impact of the head. Additionally, their skull is less rigid and the subarachnoid space smaller, leading to greater kinetic forces imparted to the brain parenchyma. Given the predisposition of children to TBI, careful assessment of the level of consciousness, pupillary examination, and neurologic examination is critical.

A GCS score can be quickly obtained with appropriate modification for young children (Table 42.2). Sternal rub should be avoided, and pressure to the nail bed is preferred. Infants with an open fontanelle will demonstrate bulging in the setting of elevated intracranial pressure (ICP) and are potential exceptions to the rule that intracranial bleeding cannot lead to hemorrhagic shock.

If there is concern for TBI on examination, clinicians can take immediate steps to reduce secondary insults of hypotension and hypoxia. Appropriate measures to ensure a stable airway, adequate oxygenation and ventilation, and appropriate resuscitation are prioritized, followed by additional measures to reduce ICP. The head of the bed can be elevated (15–30 degrees) and cervical collar assessed to ensure it is not overly tight and reducing venous outflow. Hypertonic 3% saline (3–5 mL/kg) is preferred, although mannitol is an acceptable alternative as long as its tendency to cause osmotic diuresis and hypotension is accounted for. In the setting of seizures, lorazepam, levetiracetam, and phenytoin are reasonable first-line agents.

In addition to disability, "D" should also trigger the provider to think of "dextrose." In pediatric patients, hypoglycemia can present with altered mental status and seizures, similar to the presentation of TBI, and should be included in the differential. Children who are severely hypoglycemic should be treated with IV bolus of 0.25 g/kg of dextrose (either 2.5 mL of 10% dextrose or 1 mL/kg of 25% dextrose) followed by maintenance fluids containing dextrose. Intoxication is less common in children but may also be considered as a cause for altered mental status in the appropriate circumstance.

TABLE 42.2 **Components of Glasgow Coma Scale**

RESPONSE	<2 YEARS	≥2 YEARS	SCORE
Eye	Spontaneous	Spontaneous	4
	To sound	To sound	3

	Withdraws to pain	Flexion	3
	Flexion	Extension	2
	Extension	No response	1
	No response		

Exposure and Environmental Support

Complete exposure of the patient is necessary to ensure relevant injuries are rapidly noted and subtle injuries are not missed. This is particularly important in penetrating trauma as early knowledge of entry and exit wounds can help estimate trajectory and guide decision-making. Wounds can be marked with a paper clip for x-ray identification. On imaging the number of penetrating wounds and retained bullets should add up to an even number.

Children have a relatively high surface area to body mass, making them rapidly susceptible to iatrogenic hypothermia. Even mild hypothermia can impair platelet function, inhibit clotting factors, promote diuresis, and increase oxygen consumption secondary to shivering. Cold and wet clothing should be quickly removed and warm blankets provided once the patient has been turned and a full examination, including the axilla and perineum, has been performed. Use of a forced air strategy, such as a Bair Hugger, can also be invaluable in the pediatric patient. The decision to perform a rectal examination should be based on clinical suspicion and should not be performed as a matter of course.

Secondary Survey

After completion of the primary survey, the examiner will complete an organized head-to-toe examination quickly within the trauma bay. If not already obtained, adjunctive imaging such as CXR, lateral cervical spine x-ray, and pelvic x-ray may be obtained during this time. NAT, or child abuse, is common and should always remain on the differential. Subtle findings of NAT include subconjunctival scleral hemorrhage, oral trauma such as torn frenulum, unusual bruising patterns, and enlarged head circumference. When evaluating the head of infants, it is especially important to examine open fontanelles.

Adjuncts

Catheters

Orogastric or nasogastric tubes may be helpful in select patients. Nasogastric tubes are contraindicated when a basilar skull fracture or maxillofacial instability is suspected, and orogastric tubes are indicated in this scenario. It is not unusual that a child's stomach will be filled from air, either from crying or iatrogenic introduction from positive pressure ventilation, leading to abdominal competition and hypoventilation. The naïve practitioner can be misled, leading to unnecessary imaging and/or intervention. Additionally, a functional oro/nasogastric tube may also reduce the risk of aspiration from vomiting. Rarely will placement of bladder catheters be necessary while in the trauma bay.

Imaging

Most injured children are initially (if not definitively) cared for at nonpediatric trauma centers. Thus, it is important to note that imaging of the injured child requires a thoughtful approach. The adult trauma assessment with *pan-scan* should be avoided given long-term implications of ionizing radiation in children. Choice of imaging modality is heavily guided by clinical presentation, injury location, MOI, and clinical concern.

The relative risk of radiation exposure is of particular concern in children. Young, rapidly dividing tissues are more susceptible to the effects of radiation exposure. In addition, the damage that occurs results in a cumulative lifetime risk of carcinogenesis. The majority of radiation exposure in a pediatric trauma patient is a result of CT scanning that delivers the highest radiation dose of the common imaging modalities.[10] In children, there seems to be a dose-response relationship between CT-related radiation exposure and brain cancer.[11] The "as low as reasonably achievable" (ALARA) principle can help clinicians balance the risk of radiation with the informational benefit of a given study. ALARA should guide pediatric protocols to minimize regions scanned, radiation dose, and multiphase scans and to be judicious with follow-up studies. That being said, an indicated study should not be delayed if that information is needed to guide therapy.

CXR is good at identifying thoracic pathology that requires intervention (e.g., pneumothorax, hemothorax, diaphragm rupture). CT of the chest will rarely offer clinically impactful information and should be obtained selectively.[12] However, in scenarios where there is concern for aortic injury on CXR, such as widened mediastinum, CT angiogram (CTA) of the chest is indicated. Of note, thymic tissue can masquerade as a widened mediastinum in young children.

Although FAST is a mainstay in the initial evaluation of abdominal trauma in the adult patient, it has less clinical utility in children, especially in the stable child. FAST as currently used has limited sensitivity to screen for intraabdominal injury in children sustaining blunt abdominal trauma.[13] A randomized trial of stable pediatric patients treated for blunt trauma found that FAST did not improve ED length of stay, rate of missed intraabdominal injuries, or hospital charges—leading to the conclusion that routine abdominal FAST after blunt injury in stable patients is not supported.[14] Rarely will FAST alter the management of the pediatric trauma patient, and occasionally it will misdirect or delay appropriate care. There continues to be substantial variation in the use of FAST among pediatric trauma centers.[13] Many centers use FAST in the unstable patient to rapidly assess the pericardial and abdominal cavities for sources of blood loss.

SPECIFIC INJURIES

Head Trauma

Pediatric TBI from any mechanism is the leading cause of pediatric trauma death and disability, resulting in over 60,000 hospitalizations per year.[15,16] Falls and MVCs are the most common contributors, although NAT is a major cause as well. Children <4 years of age with hypotension, low initial GCS score, and coagulopathy or hypoglycemia have particularly poor outcomes.[17] GCS can be used to categorize TBI into mild (13–15), moderate (9–12), and severe (3–8). These categories do not diagnose underlying injury, but they do provide a straightforward means of communicating neurologic status and helping providers consider immediate diagnostic and therapeutic maneuvers that should be performed.[18]

Regardless of GCS category, the overarching goal of treating TBI is preventing secondary neurologic injury that accompanies additional hypoxia and hypotension.[19–21] Preventing hypoxia requires maintaining an adequate airway to provide oxygen for gas exchange in addition to treating increases in ICP that would impair cerebral blood flow and decrease oxygen delivery. Volume resuscitation and control of bleeding are essential to maintain circulation. Sequelae of severe head injury are bound by the Monro-Kellie doctrine that recognizes the cranial vault is a rigid container and an increase in intracranial volume caused by one component (e.g., intracranial hemorrhage) must be offset by a volumetric decrease in another component (parenchyma). Displacement of cerebrospinal fluid (CSF) and venous blood can initially compensate, but once they are exhausted, ICP will increase precipitously and lead to cerebral ischemia and herniation. As such, the early manifestations of TBI—headache, irritability, vomiting—should prompt alarm because the late signs of TBI—posturing, pupillary changes, Cushing triad—can rapidly progress to significant cerebral ischemia, secondary injury, and death.

Initial Management

As with any pediatric patient presenting to the trauma bay, the initial evaluation and resuscitation should follow ATLS standards. Rapid stabilization is vital to preventing secondary brain injury from hypoxia and hypotension. After the ABCDEs of care have been addressed, neurologic status is quickly assessed by calculating GCS. A score <8 should generally prompt providers to secure a mechanical airway, initiate measures to lower ICP, and obtain a noncontrast head CT scan. In patients with mild TBI, the indications for scanning are less clear. Use of the Pediatric Emergency Care Applied Research Network (PECARN) criteria has been shown to limit the number of unnecessary head CTs by up to 60% without increasing rates of missed life-threatening injuries.[22] Importantly, all patients with loss of consciousness, skull fractures or scalp hematoma, significant MOI, and GCS <14 warrant CT without contrast. Factors such as age of the patient, loss of consciousness, and multiple injuries can be considered as well.

If there is concern for severe TBI and elevated ICP, several immediate maneuvers can be performed in the trauma bay. The head of the bed can be elevated to 30 degrees to increase venous return, and the cervical collar can be appropriately loosened to prevent outflow obstruction.[23] This is done by placing the bed in reverse Trendelenburg to allow maintenance of thoracic and lumbar spine precautions until those areas are cleared of concern. Hyperosmolar therapy with hypertonic (3%) saline will reduce intracranial edema and is preferred to mannitol, which can worsen hypotension due to its diuretic effects. Hyperventilation with $PaCO_2 < 35$ should only be performed when there is concern for active herniation and is otherwise avoided given the cerebral vasoconstrictive effect of hypocarbia. Seizure activity raises the metabolic demands of the brain and should be aggressively controlled if clinically evident. Prophylactic antiepileptic therapy reduces early (<1 week) posttraumatic seizure activity and can be considered in the setting of intracranial bleeding, age <4 years, depressed skull fracture, concern for abusive head trauma, and GCS <8.

Once the patient has been hemodynamically stabilized, the primary and secondary survey completed, and seizure activity controlled, a noncontrast head CT should be performed as soon as possible if clinically indicated. Patients with ongoing intracranial processes may look well until precipitously declining, making timely transfer to the CT scanner critically important.

Medical Management of Refractory Elevated Intracranial Pressure

Regardless of the cause of injury, prevention and management of intracranial hypertension is key in the care of children with TBI. Patients with GCS <8 and a nonsurgical lesion on CT may be candidates for an ICP monitor. An external ventricular drain allows both monitoring of ICP and therapeutic drainage of CSF, while modern intraparenchymal monitors provide additional information such as cerebral oxygen saturation and temperature. The general goals of therapy are ICP <20 mm Hg and cerebral perfusion pressure >40 mm Hg. The benefits of ICP monitors must be carefully weighed against the risks of bleeding and infection associated with their use. A recent review of over 3000 patients demonstrated no survival advantage for ICP monitoring for patients with severe TBI.[24] All patients with concern for severe TBI must be admitted to the pediatric intensive care unit (PICU) for close neurologic monitoring.

If initial measures fail to adequately address ICP, sedation and analgesia should be provided to lower cerebral metabolic demand. Neuromuscular blockade can be instituted to prevent shivering and improve ventilator synchrony. Because neuromuscular blockade prevents ongoing neurologic examinations and may mask seizure activity, continuous electroencephalogram monitoring is generally recommended. Additional options include barbiturate infusion and higher levels of hyperosmolar therapy. At one of the authors' institutions, 3% hypertonic saline is given in 5 mL/kg doses (max: 500 mL/dose) with an infusion rate that can be titrated as high as 1 mL/kg/h.

Types of Injuries

Epidural hematomas (EDHs) typically result from damage to a middle meningeal artery or a venous bone bleed that leads to accumulation of blood between the skull and the dura.[25,26] Epidural blood cannot cross suture lines and classically presents with initial loss of consciousness followed by a lucid interval and subsequent rapid decline (Fig. 42.2A). An overlying temporal skull fracture

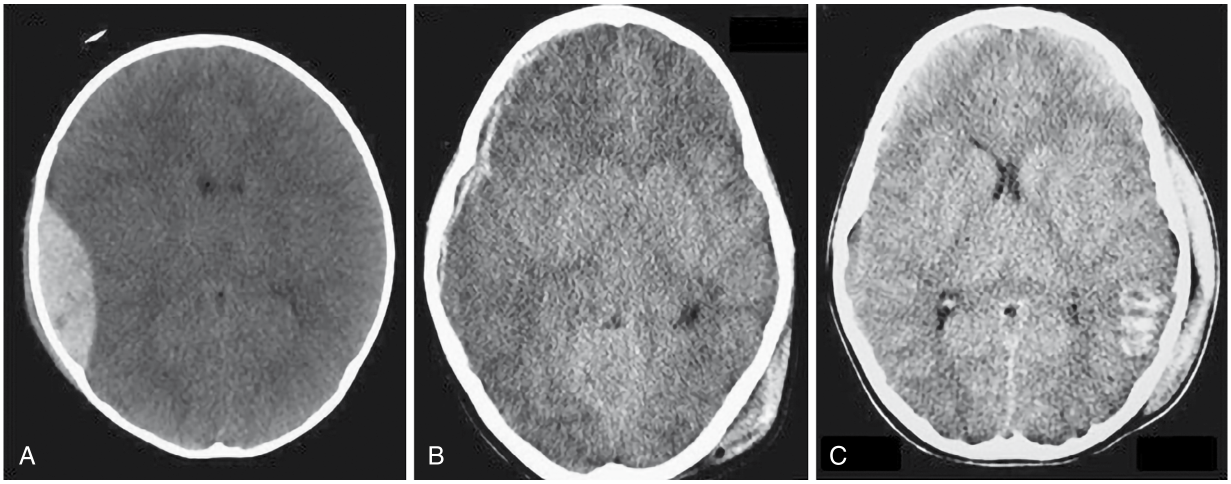

FIGURE 42.2 (A) Epidural hematoma. (B) Subdural hematoma. (C) Intraparenchymal hematoma. (From Tieves KS, Rilinger J. Traumatic brain injury. In: St. Peter S, ed. *Holcomb and Ashcraft's Pediatric Surgery*. 7th ed. Edinburgh: Elsevier; 2020:254-266; Jea A, Luerssen TG. Central nervous system injuries. In: Coran AG, Caldamone A, Adzick NS, Krummel TM, Laberge JM, Shamberge R, eds. *Pediatric Surgery*. 7th ed. Philadelphia: Elsevier Mosby; 2012:343-360.)

commonly coexists. Subdural hematomas (SDHs) are typically caused by tearing of the bridging veins that cross the subdural space. In contrast to EDH, SDHs cross suture lines and demonstrate a classic crescent moon appearance (see Fig. 42.2B). The presence of an SDH implies a substantial force imparted to the head, and patients should be closely monitored in the PICU for signs of neurologic decline that would require operative decompression. Intraparenchymal hematomas (IPHs) are acceleration-deceleration injuries that result from the brain striking the inside of the skull. IPHs tend to "blossom" in the 24 to 48 hours after the initial event, with dramatic changes often noted on interval CT scans (see Fig. 42.2C). This blossoming can worsen cerebral edema and lead to significant spikes in ICP. In the setting of significant mass effect, operative decompression will be required. Whenever an intracranial bleed is noted on CT, neurosurgery should be promptly consulted to help facilitate proper treatment.

Skull fractures are classified as linear, depressed, or basilar. Linear skull fractures are the most common but least worrisome, provided there is no underlying intracranial injury. Patients with isolated linear, nondepressed skull fractures can likely be discharged from the ED if neurologic status is normal and the patient is tolerating an enteral diet. Depressed skull fractures typically result from a more significant injury and commonly involve underlying parenchyma. Neurosurgical evaluation is mandatory, and operative intervention will likely be required in the setting of significant intracranial hematoma, neurologic deficit, or CSF leak. Basilar skull fractures involve the bones of the skull base and often coexist with injuries to surrounding structures such as the auditory canals, carotid artery, and facial nerve. If there is evidence of injury to the carotid artery, CTA of the head and neck should be considered. The McGovern score has recently been validated to further guide the evaluation for pediatric blunt cerebrovascular injury (BCVI).[27] The score incorporates physical examination and imaging findings, with a CTA recommended for all patients with a score >3. As in adults, low-grade BCVI is treated with aspirin, whereas higher grades are addressed with endovascular techniques. Before 4 years of age, the skull is relatively thin and pliable, leading to "ping-pong" fractures in which the skull is depressed inward without a clear fracture line. These injury patterns typically do not require surgery and can be monitored over time (Table 42.3).

Concussion

Concussions are TBIs that cause neurologic impairment in the absence of a gross structural injury on imaging.[28] The underlying pathophysiology involves altered permeability of cell membranes, cell rupture, axonal stretch and shearing, and disruption of synapses. Microvascular injury, vasospasm, and inflammatory responses lead to a mismatch between metabolic demand and supply. Patients may demonstrate a variety of common findings including physical, cognitive, emotional, and visual deficits. Loss of consciousness occurs with only 10% of concussions, and symptoms may take up to 24 hours to become apparent. Importantly, concussion is a diagnosis of exclusion. Patients with red flag symptoms such as persistently altered mental status, severe headache, and focal neurologic deficits must be rigorously evaluated for an underlying structural injury.

TABLE 42.3 McGovern Score

	POINTS
Glasgow Coma Scale (GCS) ≤8	1
Focal neurologic deficit	2
Carotid canal fracture	2
Mechanism of injury	2
Petrous temporal bone fracture	3
Cerebral infarction on computed tomography	3

A score >3 indicates a high risk for blunt cerebrovascular injury (BCVI) and indicates the patient should undergo angiography.

The treatment for concussion focuses on limiting metabolic demand while the brain heals.[29–31] Physical and cognitive rest for the first 24 to 48 hours after a concussion is essential to limit further cellular stress. Children should be held out of sports and restricted from activities that involve significant visual tracking such as video games and reading. Parents should be advised that concussed children may struggle with cognitive tasks they previously mastered and may require an increased need for sleep. As they recover, children will find they can tolerate increased amounts of physical and mental exertion and should be allowed to gradually increase activity with breaks as needed. Up to 80% of children demonstrate full recovery by 4 weeks, whereas others may take months to fully recover. Patients who do not recover in a predictable time frame (weeks) or have persistent symptoms are best managed by those who specialize in concussion care.

Spine

There are key differences in injury patterns, radiographic findings, and management for pediatric spinal injury compared with adults.[26,32] However, regardless of the type of injury, the first objective is to ensure cervical spine immobilization as standard ATLS assessments are underway. Subsequently, treatment focuses on addressing other injuries, particularly TBI, that may affect evaluation and treatment of a potential spinal injury.

Injury Patterns

The causes and distribution of spinal injury change with age.[33,34] In very young children, the male-to-female ratio is roughly equal, whereas in older children it is primarily male (ratio is about 4:1). Overall, about one-half of pediatric spinal injuries are caused by MVCs. Younger children are more likely to be injured after a fall, whereas older children are more likely to be injured due to a sporting or diving accident. Particularly in young children, NAT must be thoroughly considered.

Young children tend to have injuries of the upper cervical spine, whereas children older than 8 years have a distribution more similar to adults, with injuries typically occurring in the subaxial cervical spine and cervicothoracic junction.[35,36] Infants and toddlers have disproportionately large heads and weak cervical muscles, which create a greater fulcrum of motion in the cervical region. They also have greater elasticity of their posterior tension band and joint capsules with shallow facet joints and less developed uncinate processes. This allows for a greater degree of movement in all planes and transmission of energy. Consequently, 10% to 15% of spinal injuries involve "skip" injuries at multiple levels. These differences decrease linearly with age.

Injuries can be anatomically grouped into those involving the anterior, middle, and posterior columns.[33,34,37–40] Anterior column injuries are from the anterior longitudinal ligament to the midportion of the vertebral body. Middle column injuries are from the midvertebral body to the pedicles, and posterior injuries are from the pedicles to posterior tension band. Injuries can also be described as compression, burst, flexion-distraction, and fracture-dislocation. Compression fractures involve only the anterior column and do not usually have clinical deficits. Burst fractures involve the anterior and middle columns and can demonstrate neurologic deficits if a posterior portion of the vertebral body protrudes into the spinal canal. Flexion-distraction injuries involve compression of the anterior column with distraction injury of the middle and posterior columns. These injuries are commonly referred to as *chance fractures* and are often associated with a seat-belt sign and intraabdominal injury. Fracture-dislocation injuries involve all three columns with significant deformation of the spinal canal. These often result in spinal cord injury and are more likely to require operative intervention.

Initial Management and Workup

When a patient presents to the trauma bay, providers must first address the ABCDEs of trauma care before moving on to a dedicated workup of the spine. As part of the secondary survey, a more thorough examination of the spine should be performed to identify tenderness or palpable defects along the entire spine. Loss of sensation or motor function should be noted and clearly documented before the administration of any sedating or paralyzing agents. The American Spinal Injury Association (AISA) Impairment Scale can be used to help grade and characterize the extent of injury. When the mechanism is appropriate, the abdomen should be assessed for a seat-belt sign, which should heighten suspicion for a lumbar spine injury. Until spinal injury is excluded, the entire spinal axis should be immobilized and log roll precautions maintained. The disproportionately large head of young children leads to cervical flexion when they are placed on a neutral board. As such, either a specialized board or a bump placed under the torso is necessary for proper alignment. An accurately sized cervical collar is essential for both stability and patient comfort.

Imaging

The relative lack of available guidelines makes it difficult to determine when spinal imaging should be performed for pediatric patients. In the adult population, the NEXUS criteria identify patients at low risk of cervical injury who can be safely observed without imaging. The criteria include the absence of focal neurologic deficits, midline spinal tenderness, altered level of consciousness, patient intoxication, and distracting injury.[41] Given the limited ability of NEXUS to triage young children, the PEDSPINE and PEDSPINE II trials have more recently proposed easy-to-use scoring systems with high negative predictive value for cervical spinal injury in the youngest pediatric patients.[42–44] Whether plain radiograph or CT should initially be used to assess for cervical injury continues to be debated as well. The American College of Radiology recommends cervical spine radiography in children 3 to 16 years of age with at least one PECARN or NEXUS risk factor, whereas the Congress of Neurological Surgeons notes either CT or plain radiography is acceptable for initial imaging, with CT preferred for pediatric patients with suspected craniocervical junction injuries.[45,46] Atlanto-occipital dislocation (AOD) injuries are particularly devastating and can be easily missed on clinical examination. A lateral c-sine film can be useful early in the resuscitation of an obtunded patient, as identification of AOD would notably affect subsequent management.

Additionally, there are several normal radiologic findings in pediatric spines that would be considered pathologic in adults, including cervical pseudosubluxation, synchondroses, and nonvisible vertebral bodies on lateral plate studies.[47] Because of the hypermobility of the pediatric spine, up to 20% of young children have spinal cord injury without radiographic abnormality (SCIWORA), which results in neurologic deficits in the absence of vertebral anomalies.[33] MRI is a useful adjunct to detect subtle signs of injury within the cord and is superior to CT in the detection of ligamentous and soft tissue injury. MRI is most useful for obtunded or nonverbal children with suspicious injury mechanisms, equivocal radiographs or CT, or unexplained neurologic findings.[48] Experienced radiologists familiar with the pediatric spine can ensure unnecessary confusion during the trauma workup is avoided.

Management

Most pediatric fractures and dislocations can be reduced and maintained in anatomic alignment with nonoperative orthotic braces, whereas surgery is typically reserved for children with persistent deformity or ligamentous instability.[49,50] The goal of braces is to immobilize the injured segment and prevent the patient from motions that could exacerbate their injury. Early operative intervention is indicated for patients with neurologic deterioration, irreducible compression of the spinal cord, or enlarging hematoma. There are no data to support the use of corticosteroids to treat spinal cord injury. Prompt consultation with a spine surgeon when spinal injury is suspected can help ensure proper diagnostic workup and timely intervention.

Neck

An organized, rapid assessment for pediatric neck injuries is essential for initial airway stabilization and ultimate treatment of the injury.[51] Specific characteristics of pediatric anatomy can make management particularly difficult.[52,53] Compared with the adult airway, the pediatric airway is smaller and more susceptible to partial or complete obstruction from edema or hematoma. The pediatric neck is proportionally shorter with a higher, more anterior larynx and underdeveloped muscles that lead to greater transmission of forces to internal structures. Ensuring a stable, secure airway before considering imaging or therapeutic maneuvers is essential.

Initial Management

If early airway intervention is not required, providers may proceed with a focused physical examination once the initial primary survey is complete. A hematoma or bruit suggests vascular injury, whereas subcutaneous emphysema indicates aerodigestive injury. As with adult trauma, the neck is divided into three zones: zone 1 from the sternal notch to the cricoid cartilage, zone 2 from the cricoid cartilage to the base of the mandible, and zone 3 from the base of the mandible to the skull base. However, these guidelines are less reliable in children as the cricoid cartilage migrates caudally throughout childhood. As such, zone 1 injuries may be accessible through a neck incision even when below the cricoid.

Imaging

Patients with hard signs of vascular or aerodigestive injuries such as expanding hematoma, palpable thrill, and wound bubbling should proceed directly to the operating room. Selected stable patients may undergo a focused CT to assess the structures of the neck. Otherwise, patients can be considered for focused imaging based on their specific injury pattern.[54] CXR can identify concomitant pneumothorax, hemothorax, or widened mediastinum in the setting of a zone 1 injury, and cervical x-rays can help define spinal injuries. CTA of the chest and neck provides vascular detail and is most useful for stable patients with zone 1 and 3 injuries and for selected patients with a zone 2 injury. In the setting of blunt injury, the McGovern score (see Table 42.3) can be used to triage patients at high risk for BCVI and determine whether imaging is indicated.[55,56] When aerodigestive injury is suspected in stable patients, laryngoscopy, endoscopy, and esophagram can be used to identify the injured organ and facilitate operative planning.

Operative Management

Close communication with the anesthesia team is essential throughout the operation, and trauma surgeons should have a low threshold for involving a dedicated otolaryngologist. A cervical spine injury should be considered with any blunt neck trauma, and appropriate stabilization must be maintained throughout the case. If the patient is stable, a bronchoscopy and esophagoscopy should be considered before proceeding with surgical exploration. A unilateral injury can typically be accessed via an anterior incision over the sternocleidomastoid, whereas bilateral injuries are approached with a collar incision.[57] A collar incision may also be preferable in infants and toddlers because of their shorter necks. Zone 1 injuries may require sternotomy, particularly when cervical injury prevents neck extension. Zone 3 injuries are often particularly difficult to access in small children because of their relatively compressed anatomy and may require superior extension of the incision. Endovascular therapy can be used when the patient is large enough, as vessel size may be prohibitively small in younger children.[58]

Arterial injuries are addressed by first obtaining proximal and distal control of the common, external, and internal carotid. Primary repair is preferred for common carotid injuries, though extensive injuries will require repair with a patch angioplasty or interposition graft, both of which are ideally performed with a vein conduit.[59] If necessary, ligation can be considered provided there is good back-bleeding. If necessary, unilateral internal jugular vein injuries can be ligated if needed. Pediatric patients generally tolerate vascular ligation well, given the absence of underlying atherosclerosis. Esophageal injuries can be approached by retracting the carotid sheath laterally. If there is difficulty identifying the esophagus, an orogastric tube can be placed and then palpated. Devitalized tissue should be debrided, and the esophageal injury primarily repaired when possible and left. Tracheal lacerations should be repaired with a single layer of monofilament absorbable suture. More complicated airway injuries are best approached with the assistance of an otolaryngologist. A pedicled segment of strap or sternocleidomastoid muscle can be interposed between suture lines or used to buttress a repair, particularly in the setting of devitalized tissue.

Thoracic Trauma

Whereas approximately 80% of pediatric thoracic injuries result from a blunt mechanism of injury, penetrating thoracic injury is associated with a high mortality rate. Most pediatric chest injuries do not require operative intervention and need only oxygen, pain control, and possibly chest tube placement. Yet there is a subset of children whose chest injuries are life threatening and require immediate and thoughtful intervention for survival.

There are notable differences between adult and pediatric chest anatomy that warrant recognition. For one, a child's skeleton has increased compliance, allowing for the energy of impact to be transmitted to internal organs, such as pulmonary parenchyma. Whereas rib fractures are unusual in children, pulmonary contusions are common. Additionally, a simple pneumothorax may progress to a tension pneumothorax fairly quickly as the mobile mediastinum can shift rapidly, reducing venous return and compressing the contralateral lung.

Rib Fractures

As mentioned previously, given the compliance of the chest wall, rib fractures in children are relatively uncommon. When they are found, especially fractures of the first rib, a high-energy mechanism should be suspected. Flail chest is even more unusual in children. It is worth noting that rib fractures in children under 3 years old have a 95% positive predictive value (PPV) for NAT.[60] Supportive therapy is recommended for rib fractures and typically requires no other intervention.

Pulmonary Contusion

Given decreased chest wall rigidity, mechanical forces can easily be transmitted to the underlying parenchyma. Pulmonary contusions are the most frequent injury and range from asymptomatic and incidentally discovered to fatal. Although they may be identified on the CXR in the trauma bay, they may also take time to "blossom." Traumatic pneumatoceles can be associated with contusions and are relatively common. Treatment of both pulmonary contusion and pneumatoceles is supportive with judicious fluid administration. Most patients have no untoward consequence of pulmonary contusions, but there is potential to have significant V/Q mismatch and profound refractory hypoxia. Advanced ventilation strategies or even extracorporeal membrane oxygenation (ECMO) may occasionally be necessary when there are severe bilateral pulmonary contusions.

Pneumothorax and Hemothorax

The management of pneumothorax and hemothorax in the child typically mirrors that of adults. Very small and asymptomatic pneumothorax and even hemothorax may be managed expectantly without intervention. The complications of retained hemothorax, such as entrapped lung, are frequently a concern in adult trauma patients but are uncommon in children. With massive hemothorax, monitoring chest tube output is important as a large amount of blood loss (≥15 mL/kg) at the time of chest tube placement or ongoing blood loss (≥2–3 mL/kg/h for 3 hours) may be an indication for a thoracotomy. However, clinical parameters should primarily guide therapy.

Cardiac and Great Vessel Injury

Cardiac and great vessel injury is rare in children. Most cardiac injuries are blunt cardiac contusions occurring after high-energy mechanism (e.g., MVC). Initial evaluation may include measurement of serum cardiac enzymes and ECG. Contusions can lead to dysrhythmia and hypotension. Management is primarily supportive with continuous electrocardiography to monitor for cardiac arrhythmias. Echocardiogram is warranted if there is concern for rupture, valvular disruption, or cardiac failure.

Aortic and great vessel injuries are also rare in children. Most aortic injuries occur via blunt mechanism after high-speed MVC or fall from a significant height. CXR is a useful initial screening tool to evaluate pediatric trauma patients for aortic transection along with clinical presentation.[61] Widened mediastinum (although beware of thymus), indistinct or abnormal aortic contour, deviation of trachea or esophagus to the right, depression of left main bronchus, loss of the aortopulmonary window, left apical pleural cap, and large left hemothorax are findings on the initial CXR that may indicate thoracic aortic injury (Fig. 42.3). CTA of

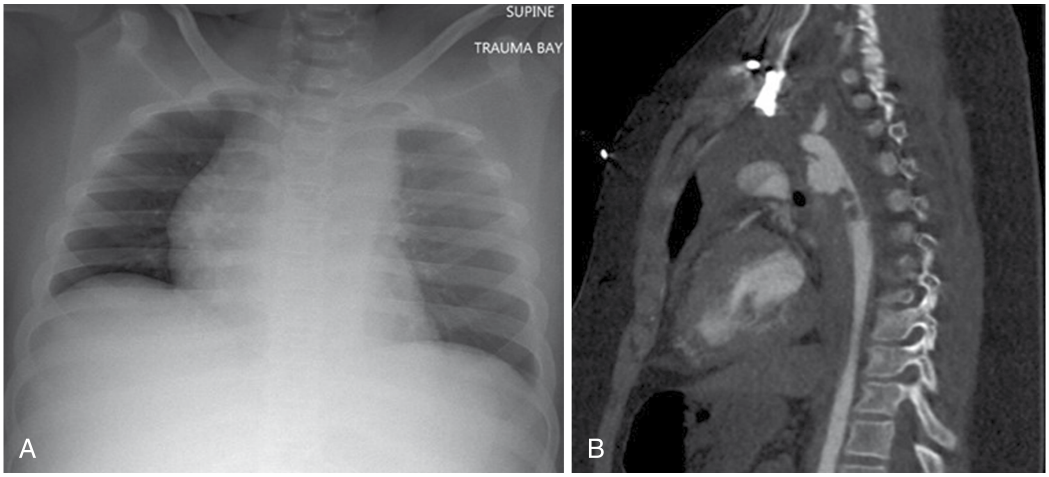

FIGURE 42.3 An 11-year-old patient after motor vehicle crash. Note chest x-ray demonstrates widening of the mediastinum suspicious for aortic injury (A) and computed tomography confirms the injury (B).

the chest is indicated if there is concern for aortic injury. Once an injury is identified, impulse control should be initiated with a β-blocker and possibly a vasodilator if needed to minimize the propagation of aortic injury with each heartbeat. Definitive management will depend on the grade of injury, age/size of patient, location and size of injured vessel, and expertise of treating center. Both endovascular and open repairs have been successful in pediatric patients.

Diaphragm Injury

Diaphragmatic injury may occur after blunt injury secondary to increased intraabdominal pressure causing rupture or after penetrating thoracoabdominal injury. After blunt injury, left-sided injuries are more common given that the liver helps to protect the right diaphragm. Classically after blunt left-sided diaphragmatic rupture a CXR will demonstrate gas-filled bowel loops or gastric bubble, possibly with a gastric tube, above the level of the diaphragm. Although most blunt diaphragmatic ruptures may occur on the left side, occasionally right-sided blunt diaphragmatic ruptures will occur after a high-energy mechanism. Right-sided diaphragmatic rupture is frequently associated with significant liver injury, and a right-sided chest tube may drain a large amount of blood from the associated liver injury (Fig. 42.4). When diagnosed acutely, diaphragmatic injury should be repaired via laparotomy given the high incidence of associated abdominal injuries. Penetrating injuries of the diaphragm may result in small, difficult-to-detect injuries and should have a high index of suspicion based on trajectory. If missed acutely, chronically there may be progressive entrapment of abdominal contents in the thoracic cavity. Chronic injuries can be repaired either through the chest or abdomen.

Asphyxia

Traumatic asphyxia occurs after a large compressive force is applied to the chest and/or upper abdomen. Venous hypertension within the superior vena cava (SVC) produces the clinical manifestations of thoraco-cervico-facial petechiae, facial edema and cyanosis, subconjunctival hemorrhage, and neurologic symptoms. Capillaries and small veins in the face, neck, and chest wall can rupture leading to petechia and conjunctival hemorrhage. The associated cerebral edema and neurologic symptoms are typically transient and will resolve with conservative measures, although long-term impairment can occur depending on period of hypoxia. Therapy includes elevation of the head of the bed, supportive care, and management of associated injuries.

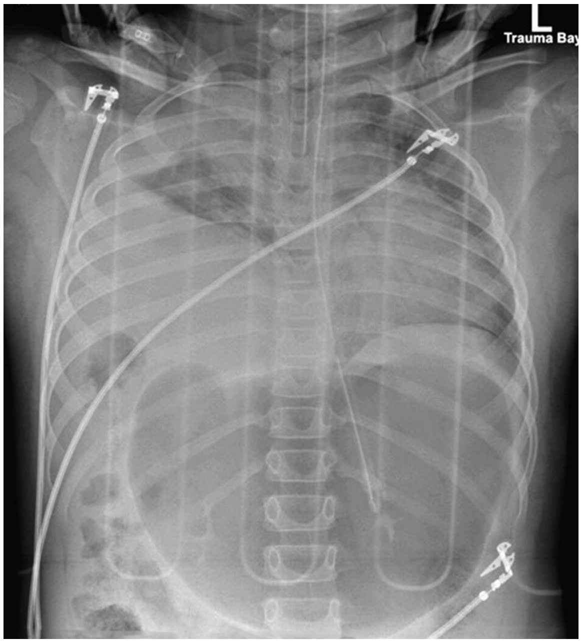

FIGURE 42.4 Right-sided diaphragmatic rupture in a 7-year-old patient after restrained-passenger motor vehicle crash. Note liver above the diaphragm and a large right hemothorax.

Abdominal Trauma

Background and Anatomic Considerations

Approximately 1 in 10,000 children sustain abdominal trauma each year.[62] Blunt trauma is responsible for up to 90% of pediatric abdominal injury and accounts for 10% of fatalities. Over half of blunt abdominal injuries occur because of MVCs, though NAT is the most common etiology in infants and toddlers.[63] Fatalities commonly occur in the setting of polytrauma, often secondary to associated TBI.

Unique anatomic and physiologic characteristics must be accounted for when evaluating pediatric abdominal trauma.[63]

Skeletal immaturity and pliability make young children more susceptible to intraabdominal injury. In particular, the spleen and kidneys are poorly protected by the less ossified lower ribcage, and the bladder rises above the protective confines of the developing pelvis. Because pediatric bones are less ossified and more pliable, significant intraabdominal injury can occur even in the absence of bony fracture. If fracture does occur, providers should suspect a high-energy mechanism and have an increased index of suspicion for concomitant intraabdominal injury. Seat belts tend ride up above the anterior superior iliac spine (ASIS) in children and transfer energy to the abdomen, increasing the risk for spine and hollow viscus injury (HVI). A "seat-belt" contusion above the ASIS should raise suspicion for intraabdominal injury.

Initial Evaluation and Diagnosis

Initial management for all patients follows standard ATLS guidelines. Once airway and breathing stability has been ensured, assessment of circulatory status is prioritized. However, significant hemorrhage in children is often masked by compensatory increases in vasomotor tone and tachycardia.[64,65] The presence of abdominal guarding or a seat-belt contusion on examination should point to the abdomen as a potential source of hemorrhage.

In the unstable patient in the trauma bay, FAST examinations may quickly help determine whether intraabdominal hemorrhage is the source of instability. However, for stable pediatric patients, FAST may have less clinical utility than in adults.[66,67] A recent trial of 975 hemodynamically stable pediatric patients with blunt torso trauma found that FAST did not improve ED length of stay, rate of missed intraabdominal injuries, or hospital charges.[68]

CT scan with IV contrast is the primary modality for identifying suspected abdominal injury in stable patients.[69] CT allows for rapid acquisition of high-resolution images, providing reliable characterization of solid organ injury. Delayed images can evaluate for extravasation from the urinary system.[70] HVI should be strongly suspected in the setting of free air or if there is free fluid in the absence of solid organ injury, although unexplained free fluid is present in at least 50% of children without bowel perforation.[71,72] Mesenteric stranding, focal wall thickening, and abnormal bowel wall enhancement may also indicate HVI.[73] A recent prediction tool was recently developed to identify patients at very low risk of intraabdominal injury in whom a CT scan can likely be safely avoided. The authors note that the absence of a complaint of abdominal pain, abnormal physical examination, abnormal pancreatic enzymes, aspartate aminotransferase (AST) >200, or abnormal CXR demonstrated a negative predictive value of over 99%.[74] From the standpoint of abdominal injury, most children with a normal CT scan can be safely discharged home from the ED.

Liver and Spleen

The liver and spleen are the most commonly injured solid organs in pediatric trauma. Injury grade alone does not dictate treatment, and nonoperative treatment strategies form the foundation of modern management protocols.[75,76] Protocols vary by institution, but for significant injury they incorporate a brief period of bed rest, serial hemoglobin laboratory draws, and ICU admission for patients with abnormal vital signs. Recent guidelines note that bed rest and serial laboratory draws are unnecessary for hemodynamically normal patients and those admitted to the regular surgical floor.[77] Patients with ongoing evidence of bleeding are monitored in the ICU with coagulopathies systematically addressed. Angiography/angioembolization can be selectively used in both the acute setting and in a delayed fashion depending on hemodynamic stability. Although extravasation should heighten the clinician's concern, therapy is guided by hemodynamics and response to resuscitation rather than imaging findings alone. Even in the presence of high-grade injuries, routine follow-up imaging is not recommended in asymptomatic children. Operative intervention is necessary in the setting of ongoing instability that cannot be safely managed through nonoperative means. In the setting of splenic injury, every effort should be made to prevent splenectomy, given the subsequent risk of overwhelming postsplenectomy sepsis (OPSI), but splenorrhaphy is rarely successful once an injury fails nonoperative management. Patients who undergo splenectomy must receive vaccinations for encapsulated bacteria and, depending on age, prophylactic antibiotic maintenance therapy.

Pancreas

Pancreatic injuries are typically the result of blunt upper abdominal impact, of which handlebar injuries are the most common mechanism, but occasionally occur with other mechanisms such as MVC and NAT. Whereas liver and spleen injuries are treated based on hemodynamic parameters, treatment of pancreatic injury is guide by American Association for the Surgery of Trauma (AAST) injury grade.[78] Low-grade injuries without ductal involvement (grade I–II) are managed nonoperatively, whereas higher-grade injuries with ductal involvement pose more difficult management decisions. For grade III injuries with involvement of the distal pancreatic duct, early (<48 hour) spleen-preserving laparoscopic distal pancreatectomy results in faster time to full enteral diet and discharge compared with nonoperative management, but long-term data are lacking. Nonoperative management is frequently successful but is associated with higher rates of pseudocyst formation and an increased risk of readmission.[79] Grade IV and V injuries involve injury to the proximal pancreatic duct. Higher-grade injuries frequently require involvement of a multidisciplinary team, possibly with the use of adjunctive measures, such as endoscopic retrograde cholangiopancreatography (ERCP). It should be noted that the optimal management of high-grade pancreatic injuries continues to be debated, with some centers managing almost all injuries nonoperatively.

Duodenal

Similar to pancreatic injury, duodenal trauma is typically caused by handlebar injury, NAT, or MVC.[80] Retroperitoneal duodenal injuries are often difficult to detect, and high suspicion for a delayed presentation should be maintained in the appropriate clinical context. Isolated duodenal hematomas are managed nonoperatively and typically resolve within 1 to 3 weeks.[80] Total parenteral nutrition (TPN), bowel rest, and nasogastric decompression can be used until obstructive symptoms resolve and enteral feeds can be reintroduced. Duodenal perforation, which is less common, requires operative intervention, the extent of which will depend on the degree of circumferential involvement of the injury.[81]

Hollow Viscus

Patients with HVI may present with immediate evidence of free air secondary to a full-thickness perforation or may demonstrate a delayed presentation after a devascularization injury that subsequently progresses to ischemia.[82] Patients with free air, peritonitis, or instability are taken immediately to the operating room, whereas stable patients with suspicious CT findings such as unexplained free fluid, bowel wall thickening, and mesenteric stranding are closely monitored with serial abdominal examinations. When patients have worsening or otherwise unexplained abdominal pain, diagnostic laparoscopy can evaluate for occult HVI.

Penetrating Injuries

Unfortunately, penetrating injuries are increasingly common in children. Compared with blunt mechanism, penetrating injuries are more lethal, requiring thoughtful and efficient diagnosis and management. The approach to penetrating injuries in children mirrors that of adults—early identification of all wounds is critical and will guide treatment decisions. All penetrating wounds should be quickly identified with the removal of all clothing and surveying the entire body by quickly rolling the child and looking in all cracks and crevices. Typically, children do not have a large amount of subcutaneous tissue to protect underlying viscera, and penetrating wounds have high likelihood of visceral injury (Fig. 42.5). Abdominal stab wounds that penetrate fascia warrant operative exploration; whether this entails a laparoscopic or open approach is dependent on the injury, patient, and provider expertise. As a general rule, firearm injuries to the abdominal cavity universally require exploratory laparotomy.

Pelvis

Pelvic fractures are relatively rare in children, accounting for 0.3% to 4% of pediatric injuries.[83,84] The developing pelvis demonstrates greater elasticity and higher cartilaginous volume than the adult pelvis, which makes pediatric pelvic fractures dependent on high-energy forces.[84,85] Given this, children tend to have less severe fractures than adults, but mortality is similar across age groups, as the extent of associated injuries more directly correlates with overall morbidity and mortality than the pelvic fracture itself.[85,86] Pediatric pelvic fractures most commonly occur as a result of pedestrians hit by cars and are frequently associated with significant additional injuries to the brain, liver, spleen, rectum, urinary tract, and femur.

Diagnosis and Management

A standard ATLS trauma evaluation is necessary for patients with suspected pelvic fractures, which are frequently in the setting of polytrauma. After the primary survey, the pelvis is palpated for tenderness and crepitus. Pelvic stability is assessed by carefully compressing the iliac wings, although rocking of the pelvis back and forth should be avoided as it may increase hemorrhage in the setting of a fracture. Complete examination of the perineum, rectum, and urethra should be performed. The standard radiologic examination in the trauma bay is an anteroposterior pelvic radiograph. If requested by orthopedics, additional views can subsequently by performed after initial stabilization.[83] A retrograde urethrogram is performed if a urethral injury is suspected. Abdominopelvic CT is highly useful in the stable patient to assess fracture pattern, evaluate associated injuries, and plan for the operating room.

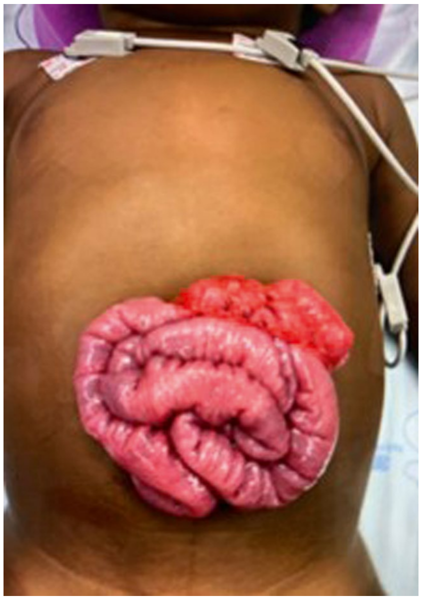

FIGURE 42.5 Infant with intestinal evisceration from abdominal stab wound.

When a pelvic fracture is suspected in the setting of hemodynamic instability, a pelvic binder can be applied in the trauma bay to reduce pelvic volume and tamponade bleeding.[87] Regardless of manufacturer, a pelvic binder should be appropriately sized and centered over the greater trochanter. If a pelvic binder is unavailable, a sheet can be used instead. If there is ongoing instability despite pelvic compression, external fixation or angiography with embolization can be performed.[88]

Most pediatric pelvic fractures are treated nonoperatively and heal without complication.[83,88] Nonoperative treatment usually entails a certain period of protected weight-bearing followed by physical therapy. Very young patients with stable fractures with acetabular extension may be treated with spica cast immobilization. Operative intervention is reserved for significantly displaced and unstable fractures of the pelvic ring. Surgery is typically performed in a delayed manner as dictated by the orthopedic surgery team.

Perineal Injury

Pediatric perineal injuries range from relatively mild superficial lacerations to severe injury with involvement of the genitourinary tract, anal sphincters, and deep soft tissue compartments. Injuries occur most frequently in the setting of MVCs, bicycle accidents, impalement, sexual abuse, and straddle injuries.[89,90] Diagnosis is often challenging given the sensitive location, but a complete assessment of the injury is critical to ensure proper treatment. The lack of external findings does not preclude rectal, vaginal, or bladder injuries. Providers should not hesitate to provide conscious sedation or general anesthesia to ensure an adequate examination is performed.[91,92] An array of additional evaluations, including proctoscopy, vaginoscopy, urethrogram, and cystoscopy, may be required based on clinical suspicion.

Management of the injury is dependent on severity and specific structures involved.[91,93–95] Combined injuries are common, and early consultation with gynecology and urology can ensure proper diagnosis and eventual treatment. Superficial soft tissue lacerations can be irrigated thoroughly and repaired with suture. Injury to the anal sphincters should be repaired primarily in the operating room, whereas more complex rectal injuries or combined anorectal and urethrovaginal injuries may require placement of a colostomy. Complex urinary tract injuries may require placement of a Foley or suprapubic catheter by urology.

Nonaccidental Trauma

Tragically, NAT is a leading cause of morbidity and mortality in the United States. Young children are at particular risk, with 80% of cases occurring in children younger than 5 years and 70% of fatalities occurring in children younger than 3 years. However, all ages are affected by physical abuse, and over 1500 fatalities are attributed annually to child abuse or neglect.[96,97]

The overarching theme in identifying child abuse is the need for a high level of suspicion and a systematic evaluation of all patients, regardless of socioeconomic status. Infants and toddlers likely will not be able to communicate a history, making it crucial to have a detailed knowledge of necessary physical examination steps, laboratory tests, and imaging studies. Regardless of injury, a multidisciplinary approach to management is necessary to address the complex immediate and long-term physical, emotional, and psychiatric needs of each patient.

Evaluation

Initial evaluation should always begin with a standard primary and secondary survey as per ATLS principles. Regardless of initial suspicions for abuse, the initial priority is stabilizing the patient. Once stable, a detailed history and physical is performed to identify any possible features suggestive of abuse. The injury itself and any other bruising are carefully documented. Even relatively minor, self-limited injuries are important potential pieces of forensic evidence. Standard trauma laboratory tests, including complete blood count (CBC), coagulation studies, electrolytes, liver function tests, and lipase/amylase, are ordered. Children younger than 2 years of age should have an x-ray skeletal survey performed to assess for fractures. A head CT should be strongly considered in children younger than 6 months in the appropriate clinical context. For children older than 2 years with a reliable examination, targeted imaging can be performed based on physical examination findings. Prior studies indicate that minority, lower health literacy, and underinsured families are more likely to be suspected of NAT, leading to higher rates of screening for abuse among these populations.[98,99] Establishing standard screening criteria and ensuring early involvement of social work and dedicated child abuse teams can minimize disparities in care.[100]

Cutaneous Injury

Bruises, bites, and burns are the most common signs of child abuse. Although isolated bruises over bony prominences are common throughout childhood, multiple bruises in different stages of healing and particularly over the buttocks, cheeks, ears, mouth, and genitalia should raise suspicions for abuse. Belt marks, handprints, and linear injuries are frequent patterns indicative of NAT. Additionally, nonambulatory children rarely have accidental bruising. Abusive burns most frequently result from scald injuries and often demonstrate splash marks and clear lines of demarcation. Immersion injuries of the buttock and genitalia often spare the flexor creases. Accidental burns are more likely nonuniform and have a story consistent with the burn pattern.

Head Trauma

Abusive head trauma is the leading cause of death and disability in children <2 years old. However, its presence may be difficult to detect as symptoms are often nonspecific and presentation is frequently delayed. Of children <2 years hospitalized for head injury, those with abusive head trauma were more likely to present with abnormal mental status and seizures, whereas children with accidental head injury were more likely to have scalp hematomas.[101] Patients younger than 2 years with isolated parietal skull fractures are more likely to be accidental, whereas complex skull fractures with intracranial injury are more often abusive trauma.[102] In a retrospective chart review of children with isolated, non–motor vehicle-related, skull fractures, children with a clear history of trauma, no extracranial injuries, and no social concerns were almost exclusively found to be accidental.[103]

Children younger than 6 months are particularly prone to shaken baby syndrome in which the infant is vigorously shaken, typically because of inconsolable crying by the infant. This results in direct trauma to the brain, SDH secondary to tearing of bridging veins, and shearing of axons.[104] Associated retinal hemorrhages and rib fractures are common. Overall, intracranial hemorrhage in children younger than 3 years has been associated with a 99% probability of abuse in the appropriate clinical context.

Fractures

Fractures are the second most common resultant injury of child abuse.[105] The most frequently injured long bones are the femur, humerus, and tibia, with fractures near the growth plate particularly suspicious for child abuse.[106] A systematic review of 32 studies demonstrated that fractures resulting from abuse were most common in patients younger than 3 years of age. Rib fractures were most predictive of abuse.[107] Multiple fractures should raise particular concern for abuse because the likelihood of abuse increases four- to sixfold for children with three or more fractures compared with those with only one.[108]

Abdomen

Although abdominal abusive injuries are relatively rare, they are the second most common cause of death after abusive head trauma. Solid organ injuries are the most common injury pattern, with the liver most frequently injured followed by the spleen. Pancreatic injuries are rarer and typically occur in conjunction with duodenal or other HVI. Patients often demonstrate bruising of the abdomen and may have elevations in liver function tests and pancreatic enzymes. In the setting of NAT, it is worth noting that the history is unreliable, so even without a reported mechanism concerning for abdominal trauma, the child should be considered a potential victim of assault, and the clinician should maintain appropriate concern for occult injury. When there is suspicion for injury, a CT with IV contrast is warranted.

Management

Although treatment depends on the specific injury pattern, a multidisciplinary approach will optimize short- and long-term outcomes. Frequently, a dedicated team evaluates all patients with suspected child abuse or neglect. This ensures all patients are seen by a team dedicated to ensuring a thorough history and physical is performed, all necessary laboratory tests are drawn, imaging studies are performed, and the workup is completed in a manner that minimizes bias.

Musculoskeletal

General

Musculoskeletal trauma accounts for 10% to 15% of all childhood injuries.[109,110] Fifty percent of males and 25% of females suffer a fracture before age 16, with a peak incidence in both groups at 10 to 14 years.[111,112] Fracture location varies with age in a manner that reflects underlying skeletal maturation and age-specific activities. The capacity of the pediatric skeleton to grow and rapidly remodel allows many of these fractures to be treated nonoperatively, whereas similar injuries in adults would require surgery.

Normal skeletal growth depends on the physes (growth plates) located at the ends of the long bones and vertebral body endplates.[113] The growth plates are the weakest point of the skeleton and account for roughly 30% of long bone fractures.[109] Improper treatment can lead to deformity or cessation of development. The

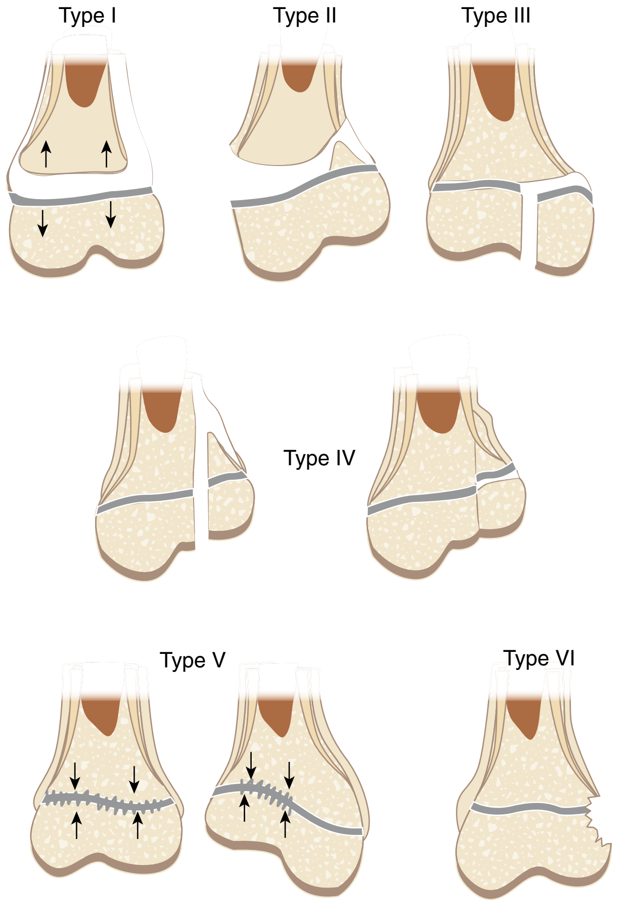

FIGURE 42.6 Salter-Harris classification system for physeal fractures. (From Leschied JR, Soliman SB. Pediatric musculoskeletal trauma: special considerations. *Semin Roentgenol.* 2021;56:70-78.)

Salter-Harris classification system is used to describe physeal injuries and predict outcomes (Fig. 42.6).[113,114]

The possibility of NAT must be accounted for in all pediatric fracture workups.[110,112] Abuse is especially common when the fracture pattern does not fit the reported history, the child is under 18 months of age, and there are fractures in different stages of healing.

Lower extremity. Femur fractures are the most common pediatric fractures requiring hospitalization.[115,116] In children younger than 1 year, up to two-thirds of femur fractures are secondary to child abuse, whereas fractures are commonly caused by falls in children aged 2 to 3 years and MVCs in older children.[117] A fracture of the femoral shaft in a nonambulatory infant should raise particularly high suspicion for child abuse, especially with transverse fracture patterns. Anteroposterior and lateral radiographs of the femur, hip, and knee are usually sufficient, although CT and MRI may be selectively used to evaluate more complex fractures or those requiring surgical management.[112] In general, young children are often treated nonoperatively with closed reduction, older children with flexible nails or plates, and adolescents more similarly to adults with solid femoral nails.[118–120]

Proximal tibial physeal injuries typically involve high-energy mechanisms and require careful vascular examination to detect injury to the popliteal artery. By contrast, nonphyseal fractures of the tibia and fibula occur as a result of lower-energy mechanisms and are much more common. Regardless of the specific fracture location, patients should be closely monitored for the development of compartment syndrome, with a low threshold for fasciotomy given adequate clinical suspicion. Most fractures to the tibia and fibula can be treated nonoperatively, though patients with open fractures and significant malalignment will require surgery.[121,122]

Upper extremity. Clavicular fractures in pediatric patients are common, typically uncomplicated, and usually adequately treated by sling immobilization alone.[109] Injuries to the medial clavicle have the potential to compress mediastinal structures. They must be promptly evaluated by CT or MRI and will likely require open reduction with careful evaluation of deeper structures.[123–125]

Fractures of the proximal humerus are usually treated nonoperatively, as rapid growth leads to predictable remodeling in all but the most angulated fractures.[126,127] Older adolescents might require surgery if they have insufficient remaining growth potential. In the distal humerus, a supracondylar fracture is the most common injury and typically results from a fall on the outstretched hand. A thorough neurovascular examination is critical to detect impingement of the median nerve and brachial artery, which would require immediate operative reduction.[128,129] In the growing elbow there are multiple centers of ossification, which can make identification of a fracture difficult. A comparison radiograph of the contralateral elbow can help distinguish normal growth patterns from an occult fracture.

Distal forearm fractures are typically treated with closed manipulation and casting, often under conscious sedation. After reduction, the extremity is immobilized in a sugar tong splint or bivalved cast to account for early swelling. When the shaft of the radius or ulna is involved, internal fixation is often required to maintain stabilization. Generally, once the fracture is stabilized, the child should be relatively comfortably with a tolerable pain level. Pain out of proportion to the fracture should raise alarm for developing compartment syndrome.

Most hand injuries can be adequately diagnosed and treated with a careful history and physical examination alone.[130,131] The hand should be manipulated gently, with careful attention to neurovascular status. Plain films are commonly ordered to evaluate bony abnormality or foreign body. Ultrasound can assess tendons, foreign bodies, and fluid collections, whereas CT and MRI are more useful for evaluating complex injuries. Typically hand and wrist injuries can be managed nonoperatively with appropriate manipulation and casting, with exceptions for open and severely angulated fractures. In the setting of a traumatic amputation, the amputated part should be wrapped in saline-moistened gauze, placed in a container containing a slurry of ice and water, and quickly evaluated by a hand specialist for reimplantation.

Burns

Although care for burn and inhalational injuries has dramatically improved in recent decades, these injuries remain complex with the potential for substantial morbidity and mortality.[132,133] Children younger than 2 years old are at particular risk of morbidity given their relatively thin skin, which leads to more severe burns given the same thermal exposure.[134–136] Furthermore, a larger surface area to body mass ratio places young children at particularly high risk of insensible fluid losses, and their immature kidneys require larger fluid volumes for adequate resuscitation. Scald injuries, whether accidental or abusive, are the most common injury in younger children, whereas flame burns are more common in teenagers. Given the severe physiologic consequences of burns, a multidisciplinary approach is critical to ensuring initial stabilization, short-term resuscitation, and long-term rehabilitation.

Initial Evaluation

All patients with large burns (>10% total body surface area [TBSA]) should undergo initial ATLS evaluation, with special attention paid to other traumatic injuries in addition to the burn.[137] During the primary and secondary surveys, the burned area should be covered with a dry sheet and attempts at debridement deferred. Close attention should be paid to the evaluation of the airway, and a decision to intubate a tenuous patient should be made quickly.[138] The small cross-sectional area of the pediatric airway makes it susceptible to rapid collapse in the setting of worsening edema.[7] Signs such as increased respiratory effort, stridor, and hoarseness are ominous and should prompt rapid intervention. If there is uncertainty, fiberoptic bronchoscopy is the gold standard for evaluation of the airway. Whenever there is concern for inhalational injury, patients should receive 100% oxygen empirically while an arterial blood gas and carboxyhemoglobin levels are obtained. Carbon monoxide poisoning will falsely elevate pulse oximeter readings, making it necessary to review laboratory values to assess tissue oxygenation. As the airway is secured, two large-bore IVs and a Foley catheter should be placed with resuscitation promptly started. Reasonable urine output goals are 0.5 mL/kg/h for patients >30 kg and 1 mL/kg/h for patients <30 kg (Fig. 42.7).

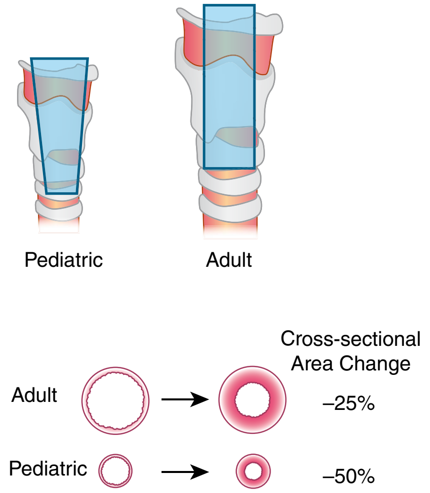

FIGURE 42.7 Cross-sectional area of pediatric and adult airways.

Once the primary survey is complete, providers should accurately measure the %TBSA of the burn and determine whether transfer to a burn center is warranted.[139] Superficial burns involve only the epidermis and are not included in calculations of %TBSA. They are erythematous and painful and heal relatively quickly. Partial-thickness injuries are considered either superficial or deep depending on whether they involve only the superficial papillary dermis or if they extend deeper to the reticular dermis. Superficial partial-thickness burns are erythematous, blanch readily to pressure, are painful, and tend to blister. Deep partial-thickness burns are less sensate, less erythematous, and less likely to blanch. Burns extending through the dermis to deeper tissues are classified as full thickness. Although the rule of nines can be used in older teenagers to calculate %TBSA, modifications are necessary for younger children (Fig. 42.8). The American Burn Association recently published guidelines to help determine the necessity and timeliness of burn center transfer.[140] They note that patients with inhalational injury; full-thickness burns; partial thickness ≥10% TBSA; and burns to the face, hands, genitalia, feet, perineum, and joints should all receive strong consideration for transfer.

Inhalational Injury

Inhalational injury results from damage to the upper airway by heated air and to the lower airway by inhaled smoke. In the oropharynx this leads to erythema, ulceration, and worsening edema. Below the vocal cords, this leads to substantial epithelial injury, alveolar damage, and increased pulmonary vascular resistance. Normal ciliary clearance mechanisms are impaired, leading to accumulations of airway debris and secondary infection.

Further systemic morbidity may result from carbon monoxide (CO) and hydrogen cyanide (HCN) toxicity.[141,142] CO has a 200 times greater affinity for hemoglobin than oxygen, causing a left shift of the oxygen dissociation curve. Patients will have a normal pulse oximeter reading but substantial deficits in tissue oxygenation. Carboxyhemoglobin (COHb) blood levels should be quickly obtained in all patients suspected of inhalational injury. At low COHb levels, patients may develop headaches, blurred vision, nausea, and vomiting. At higher levels, seizures, loss of consciousness, and impaired respirations can occur. In patients with suspected CO poisoning, initial management should be placing child on 100% humidified high-flow oxygen to decrease the half-life of COHb. HCN is released due to the combustion of synthetic household products and disrupts aerobic metabolism by binding to mitochondrial cytochrome c oxidase. Patients develop neurologic deficits, persistent acidosis, and elevated lactate levels despite appropriate resuscitation.

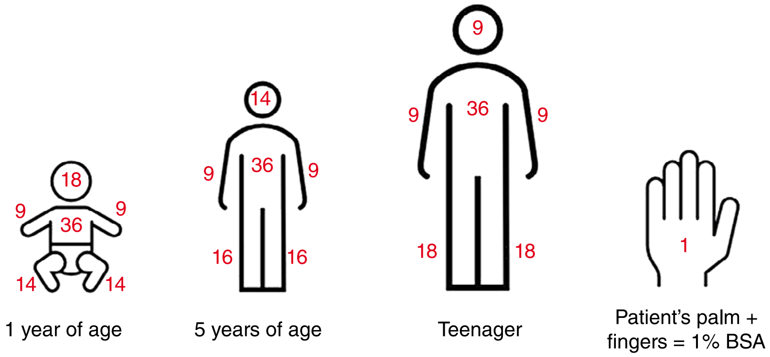

FIGURE 42.8 Percent body surface area of each body part by age. *BSA*, Body surface area. (Adapted from Duggan RP, Palackic A, Branski L. Burns. In: Mattei P, ed. *Fundamentals of Pediatric Surgery*. Cham: Springer; 2022:223-240.)

Hydroxocobalamin can be administered to bind and metabolize cyanide for excretion in the urine.

All patients with inhalational injury should receive aggressive supportive care with aggressive chest physiotherapy, clearance of secretions, and early mobilization. Inhaled heparin, acetylcysteine, and racemic epinephrine can facilitate the breakdown of fibrin plugs, improve clearance of secretions, and minimize bronchospasm. Chest wall oscillation and bronchoalveolar lavage can further assist in removing secretions and collecting microbial specimens.

Burn Resuscitation

Burns cause severe physiologic impairments secondary to substantial cellular derangements and increased capillary permeability.[143,144] Underresuscitation leads to decreased cardiac output and end-organ damage, whereas overresuscitation leads to fluid creep, pulmonary edema, and compartment syndromes.[145,146] Finding the right balance is challenging and requires constant reassessment of the patient's examination, urine output, and laboratory values. Doing so is made more difficult by the changes in total TBSA relative to overall mass as the pediatric patient develops. The Parkland formula that is used for adults tends to underresuscitate children with minor burns and substantially overresuscitate large burns. The Cincinnati and Galveston formulas better account for TBSA variability in pediatric patients (Table 42.4).[147,148] Regardless of the formula chosen, fluid resuscitation should begin even before the %TBSA burned is calculated. Two large-bore IVs are placed, resuscitative fluids started, and a Foley catheter inserted. The total fluid to be given over the next 24 hours is then calculated, with constant adjustments made based on serial assessment of vital signs, mental status, physical examination findings, and laboratory values.

Burn Wound Management

Burn wound management varies substantially depending on the depth and size of the wounds. Superficial wounds typically heal without surgical intervention within 10 to 14 days and can be managed nonoperatively with dressings and topical agents. Traditionally, antimicrobial agents such as silver sulfadiazine, mafenide acetate, and silver nitrate were used for partial-thickness wounds to create a moist environment and prevent infection of the wound. In many centers, these agents have been largely replaced by synthetic and biologic wound dressings that require less frequent changes and improve healing time.[149] Deep partial-thickness burns require excision and grafting if the surgeon does not anticipate healing within 3 weeks, although differentiating superficial and deep partial-thickness wounds can be challenging. Wound biopsy and laser Doppler imaging can help providers more reliably assess depth.[150,151] If the burn is less than 20% TBSA, it can be initially managed conservatively until depth is accurately determined. Full-thickness burns should generally be excised and grafted within the first 24 to 48 hours.

Burn wounds are typically excised tangentially, using a dermatome or VersaJet water dissector, and then grafted using autograft skin.[152] Autografts are either split or full thickness depending on the depth of tissue harvested. Full-thickness grafts have better cosmetic results and are used for facial, hand, genital, and joint burns. Full-thickness donor sites are limited to tissues that can be closed primarily such as the inguinal and postauricular regions. Split-thickness grafts are used for burns that cover a more extensive area. Grafts can be meshed to increase coverage and allow better drainage of hematomas and seromas. If donor sites are not available, burns can be temporarily covered with a dermal substitute to minimize fluid loss and reduce pain.[153] A split-thickness skin graft can be subsequently applied on top of the substitute.

TABLE 42.4 Pediatric Resuscitation Formulas After Burn Injury

Cincinnati formula	Young children: • 4 mL/kg/% TBSA burn + 1500 mL/m^2 total BSA of LR. • Half over the first 8 h, half over the next 16 h. • First 8 h, 50 mEq/L of sodium bicarbonate is added. Second 8 h is LR alone. Third 8 h, albumin (12.5 g of 25% albumin per liter of crystalloid) is added. • 5% dextrose as needed. Older children: • 4 mL/kg/% TBSA burn + 1500 mL/m^2 total BSA of LR. Half of the volume in the first 8 h, followed by remainder in 16 h. • 5% dextrose as needed.
Galveston formula	LR: • 5000 mL/m^2 burn + 2000 mL/m^2 total. Half of the volume in the first 8 h, followed by remainder in 16 h. • 12.5 g of 25% albumin per liter of crystalloid. • 5% dextrose as needed.

BSA, Body surface area; *LR,* lactated Ringer; *TBSA,* total body surface area.

Injury Prevention and Advocacy

Injury is the leading cause of death and disability in children worldwide. In fact, more than 60% of deaths among children and adolescents in the United States result from injury-related causes.[154] The most frequent MOIs include falls, MVCs, sports injuries, abuse, and firearm-related injuries. In 2020, firearm-related injuries surpassed all other causes as the most common cause of death for children in the United States.[155] Addressing these causes of injury is a key focus of trauma surgeons—in addition to the critical work of caring for injured children. This focus on injury prevention is recognized as being of such importance that it is a requirement of certification by the American College of Surgeons as a level I trauma center.

Efforts to prevent injuries must acknowledge that the burden of injuries is not borne equally by all children in the United States, with significant inequities in who is injured and how severe those injuries are. These inequities are associated with both individual and neighborhood-level social determinants of health (SDOHs).[156–158] As such, the SDOHs are key upstream targets in injury prevention efforts.

Injury prevention efforts can be divided into three primary categories: primary, secondary, and tertiary prevention.[159] Primary prevention focuses on preventing disease before it happens through modification of existing risk factors and prevention of development of risk factors. Examples of primary prevention may include provision of bike helmets, car seats, gun locks, and other home safety equipment (e.g., baby gates) to reduce the likelihood that a child is injured.[160,161] Secondary prevention addresses recovery from injury to prevent additional injury and works to modify risk factors identified after the injury that put the child at risk for future injury. This may include particular work around firearm safety after a child sustains an unintentional injury while handling a loaded firearm. Tertiary prevention focuses on mitigating long-term effects from injury and may include addressing acute stress or posttraumatic stress after injury.[162]

Each of these areas is seminal in reducing and preventing the impact of injury on child health and wellness as well as the health of the family and community more broadly. Injury prevention efforts are integrally linked with advocacy by all providers who care for children. Such advocacy focuses on increasing resources allocated to injury prevention within healthcare systems as well as changing laws and regulations on the local, state, and national level to reduce risk. Examples of successful efforts include legislation for bike helmet laws and child access laws for firearm safety, among others. These legislative changes have been shown to clearly reduce injuries in children.[163] These must also be tied to efforts to improve the mental health of children, as there are clear linkages between worsening mental health and rising suicide rates among children as well.[164] Recognizing that inequities in injuries overall, and firearm injuries in particular, are rooted in longstanding structural racism, addressing such structural factors is critical to the success of injury prevention strategies. This also requires recognition that community-level violence is a complex, dynamic challenge that requires tools that acknowledge these systemic factors.[165]

Injury prevention endeavors are a key focus of trauma systems to reduce the devastating short- and long-term impact of injuries on children, their families, and their communities.

Summary

INTRODUCTION

Overall, surgery has evolved at a remarkable pace over the past three decades. The world witnessed a transition to minimally invasive approaches, moving from open procedures to laparoscopic and now robot-assisted procedures. In addition, principles of enhanced recovery are now the standard of care in many subspecialties. However, the field of burn surgery has lagged behind until just recently. Early excision, metabolic management, and dermal template advances pushed the field forward 40 to 50 years ago, but since then only a few additions such as better ventilator management and the appropriate use of renal support emerged. Importantly, new efforts for improved resuscitation techniques and novel skin replacement technologies have returned to center stage (Fig. 43.1).

Progress in our field has been somewhat limited in the marketplace of ideas by the decreasing incidence of severe burns in the developed world; unfortunately this is not the case worldwide. Disparate patterns of care remain across centers, and training has wide variability in content related to less emphasis on burns in surgery overall. Further, difficulty remains in performing high-quality prospective studies given the heterogeneity of burn wounds and unmeasured confounders in these complex patients. However, recent concerted efforts to develop agreeable clinical practice and training guidelines, expansion of regenerative medicine technologies, and a commitment to high-quality study performance have resulted in a new push forward. For example, training guidelines for fellowships with on-site review have now been established by the American Burn Association. Further, a point-of-care autologous skin cell suspension allowing 80:1 expansion, dermis-sparing enzymatic excision of wounds, and novel bioengineered cell constructed skin substitutes now allow for earlier closure of wounds and less use of conventional skin grafts.[1] Improvements in diagnosis with new imaging technology have also come to the fore. Finally, a portfolio of positively disruptive technologies has been funded by the US Department of Defense (DoD) and Biomedical Advanced Research and Development Authority (BARDA), resulting in significant strides forward. The field continues to merge with the aim to maximize survival with a push for high-value, multidisciplinary, patient-centered care with optimal functional and cosmetic outcomes coupled with reintegration back into society. Rehabilitation is no longer considered "aftercare" and starts immediately after injury.

To review the field of burn care, both established and emerging, this chapter covers burn epidemiology, pathophysiology, burn treatment paradigms, and new technologies that are rapidly becoming standard of care.

GENERAL CONSIDERATIONS

In 2020, approximately 290,000 people were burned in the United States, 4000 of whom died (overall mortality rate 1.4%).

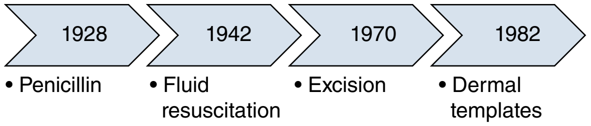

FIGURE 43.1 Evolution of burn surgery.

Epidemiologic trends from 2001 to 2021 demonstrate that the US population grew from 285,000,000 to 332,000,000 people, a nominal 16% increase. Correspondingly, the incidence of burns diminished from 520,000 to 290,000, a 43% decrease. However, the number of fatal burns has increased with an inflection point in 2012, from 2500 deaths in 2001 to 4000 deaths in 2021.[2] From these data, we conclude that the number of burns has appreciably decreased per capita over this period; however, the population (aka "capita") continues to increase nominally; thus, burns remain a steady public health threat (Fig. 43.2). When separated into children (0–18 years), adults (19–65 years), and the elderly (>65 years), these trends remain, decreasing mostly in children and young adults with moderate decreases per capita in older adults and the elderly. However, over this period the number of deaths caused by burns has significantly increased, which is of concern. This is particularly true for the elderly. Thus, prevention strategies have been successful, but mortality outcomes in those who are burned are going in the other direction.

Fortunately, most burn cases are mild to moderate and are commonly treated in the outpatient setting. However, approximately 40,000 burns per year in the United States are severe enough to undergo inpatient hospitalization for treatment.[2] It is estimated by the Centers for Disease Control and Prevention that the annual direct medical costs for burn care was $2.64 billion in 2020. What is more striking is the estimates of work loss and quality-of-life costs at $3.46 billion, for a total annual cost of $5.79 billion; the average cost of hospitalization for burns is $68,000, with ongoing costs after discharge at $89,000 per patient (total $157,000 per patient). For context, in 2020, about 7% of the US population suffered some form of injury and received recorded treatment, but few sustained fatal injuries (1.3% of those injured). For comparison, deaths in those with burns represented 1.4% of all injury fatalities, which accords with injury overall.

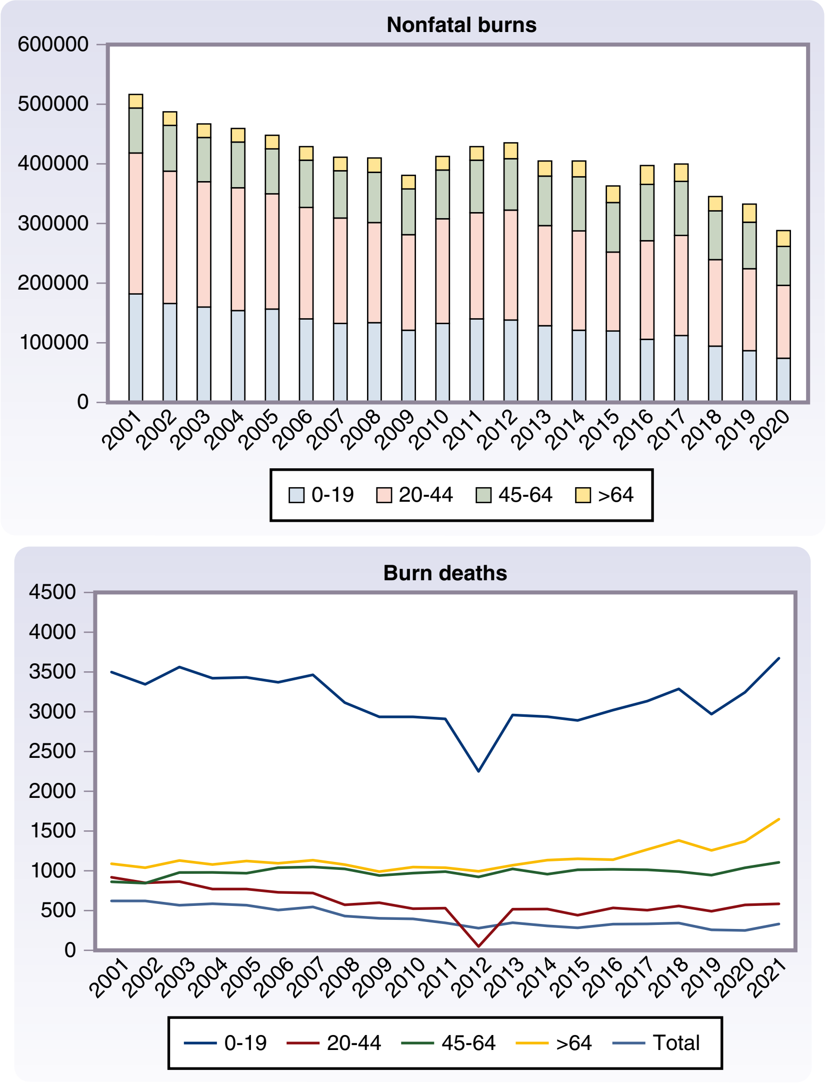

FIGURE 43.2 US burn incidence rate (2001–21). Groups are stratified by ages in the legend. (Top) Nominal numbers of burns cited in the WISQARS database from the US Centers for Disease Control and Prevention. (Bottom) Nominal number of deaths related to burns in the same database.

Burn deaths generally occur in a bimodal distribution, either immediately after the injury or weeks later as a result of multiple organ failure, a pattern similar to all trauma-related deaths and in keeping with the maxim espoused by Basil Pruitt: "burns is the universal trauma model." Therefore, burns remain a major morbid problem in the United States as a representative of high-income countries. However, it is much worse in low- and middle-income countries.[3]

Approximately 43% of burns in the United States are caused by fire and flame, 34% from scalding with hot liquid or grease burns, 9% from contact burns, 3% from chemical burns, and 4% from electrical burns.[4] Three-quarters of all burns occur at home and commonly involve children less than 10 years of age, adult males, and, increasingly, the elderly. In a 10-year average from 2011 to 2020 in the United States, 30% of burns occurred in the 0- to 19-year-old age group (children) and another 41% in the 20- to 44-year-old adult age group. The rest were in older adults aged 45 to 64 (22%) and persons over 64 years of age (7%). In terms of sex, 54% of burns in the United States occur in males, which is a more equitable sex distribution than found previously.

Seventy-five percent of all burn-related deaths occur in house fires commonly associated with food preparation or heating equipment. Interestingly, the cause of fire with the highest mortality is still from cigarette smoking, which leads to 22% of house fire–related deaths. Young adults are frequently burned with flammable liquids, whereas toddlers are often scalded by hot liquids at a proportion of 60%. A significant percentage of burns in children are the result of child abuse. Other risk factors include low socioeconomic class and unsafe environments.[5] These generalizations emphasize that most burn injuries are preventable and therefore amenable to prevention strategies.

A recent probit analysis on the overall mortality from burns regardless of age in the United States showed an LD_{50} at a 55% total body surface area (TBSA) burn; therefore, in current times, a 55% TBSA burn has a 50% probability of death. When a similar analysis was done with Baux score (age + TBSA burned) accounting for improved survival probability in younger age groups, the LD_{50} was 105 and LD_{90} was 130.[5]

Prevention strategies have decreased the number and severity of injuries. Successful approaches include legislation for fire-safe cigarettes and some cultural transition to e-cigarettes—although e-cigarettes are not without fire risk associated with battery ignition, they do decrease the rate of structure fires. Other effective events were changes in the National Electrical Code, elevation of hot water heaters from the ground, and increased smoke alarm use, which have significantly decreased fire death rates.

Burn Units

Improvements in burn care originated principally in specialized care units dedicated to burned patients, first developed in the United Kingdom during WWII by Gilles and MacIndoe. These consist of experienced personnel with dedicated resources to maximize outcome from these devastating injuries (Box 43.1). The American Burn Association currently provides a program to verify whether burn units meet a series of qualifications for personnel, space, equipment, supplies, and processes to secure best outcomes, with over 90 verified burn centers currently in the United States.[6] They also recommend that patients with the following criteria be referred to a verified burn center:

1. Partial-thickness burns greater than 10% TBSA
2. Burns involving the face, hands, feet, genitalia, perineum, or major joints
3. Any full-thickness burn
4. Electrical burns, including lightning injury
5. Chemical burns
6. Inhalation injury
7. Burns in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect outcome
8. Any patient with burns and concomitant trauma (such as fractures) in which the burn injury poses the greater immediate risk of morbidity and mortality. In such cases, if the trauma poses the greater immediate risk, the patient may be initially stabilized in a trauma center before being transferred to a burn unit. Physician judgment is necessary in such situations and should be in concert with the regional medical control plan and triage protocols
9. Burned children in hospitals without qualified personnel or equipment to care for children
10. Burns in patients with poorly controlled pain

BOX 43.1 Burn Unit Organization and Personnel

- Experienced burn surgeons (burn unit director and qualified surgeons)
- Dedicated nursing personnel
- Physical and occupational therapists
- Social workers
- Dietitians
- Pharmacists
- Respiratory therapists
- Psychiatrists and clinical psychologists
- Prosthetists

PATHOPHYSIOLOGY OF BURNS

Local Changes

Thermal burns cause damage to the skin and occasionally underlying structures through abrupt temperature change exceeding biologic tolerance. Membranes disrupt, protein denatures, and necrosis results. The injury extends from the skin surface to deeper structures in a first-order logarithmic distribution depending on the temperature of the burning agent and duration of exposure. Severe burns to the skin reaching over 280°F on the surface induce a Maillard-type reaction, with changes in consistency and color common in flame full-thickness burns. Burns that induce necrosis of the surface with temperatures below 280°F, such as scald burns from hot water, have a different appearance and texture and can be mistaken for partial-thickness burns. The thermal conductivity of the causative agent for scald and contact burns also affects the depth, which is typically by conduction rather than convection or radiation common with flame burns, particularly those sustained during explosions. Thermal conductivity is the ability to transfer heat; for water, it is 0.61 W/m/°C; for hot cooking oil, it is 4.2 joule/g/°C; and for grease, it is 1.8 joule/g/°C. Therefore, with cooling being the opposite of heating, more energy is transferred more rapidly. From a public health perspective, it is important to encourage patients to keep appropriate (class A, B, and C for residential and K for commercial) fire extinguishers in the kitchen for injuries associated with hot oil and grease. Grease fires should be extinguished by putting a lid on the pan or using a fire extinguisher. Persons should never attempt to extinguish the flame with running water, and they

BOX 43.2 Burn Classifications

Causes of Injury

Flame—damage from superheated oxidized air by convection and radiation
Scald—damage from contact with hot liquids
Contact—damage from contact with hot or cold solids
Electrical—conduction of electrical current through tissues
Chemical—contact with noxious chemicals
Friction—shearing injury from moving belts or contact with the ground at velocity

Depth of Injury

Superficial—injury confined to the epidermis
Superficial partial-thickness—injury to the epidermis and papillary dermis
Deep partial-thickness—injury to the epidermis and reticular dermis
Full-thickness—injury extending through the epidermis and dermis into subcutaneous fat

should be discouraged from carrying a flaming pan of grease outside to throw it in the yard because this is how most injuries occur.

Burns are classified into six different causal categories and four depths of injury (Box 43.2). The causes include injury from flame, hot liquids (scald), contact with hot or cold objects (contact), conduction of electricity, chemical exposure, and friction. The first three induce cellular damage primarily by transfer of energy, inducing coagulative necrosis (except for cold injuries, which do not cause protein denaturation). Electricity and chemicals cause direct injury to cellular membranes in addition to the transfer of heat, and finally, friction is by direct shearing forces.

The skin provides a robust barrier to transfer of energy to deeper tissues; therefore, much of the injury is confined to this layer. Further, and as mentioned previously, transfer of energy generally follows a first-order distribution; thus, distance from the source induces logarithmic decreases in energy transmission. Time is also a key component, with direct correlation to the severity and depth of the injury. This is important to note because people often attempt to quickly remove themselves from environments where burns occur, thus limiting the severity of injury. Considering this in the history of the event is important in determining wound depth and thus optimal treatment.

After the inciting focus is removed, the response of local tissues often leads to injury in the deeper layers. The area of cutaneous injury has been divided into three zones: zone of coagulation, zone of stasis, and zone of hyperemia.[7] The necrotic area of burn where cells were directly disrupted is termed the *zone of coagulation;* this tissue is irreversibly damaged at the time of injury. The area immediately surrounding the necrotic zone has a moderate degree of initial insult that is worsened with decreased tissue perfusion. This is termed the *zone of stasis* and, depending on the wound microenvironment, can either survive or go on to coagulative necrosis. The zone of stasis is associated with vascular damage and vessel leakage. The last area is termed the *zone of hyperemia,* which is characterized by vasodilation from inflammation surrounding the burn wound. This region contains the clearly viable tissue from which the healing process begins and is generally not at risk for further necrosis. This concept, termed *the Jackson Levels,* has been questioned recently with the development of new molecular and imaging techniques for measurement of the process, although it remains the basis for the physiologic description of burn wound progression and results.[7]

Burn Depth

Burn depth depends on the initial tissue damage, classified by penetrance from the surface to the epidermis, dermis, subcutaneous fat, and underlying structures (Fig. 43.3). Superficial burns (previously termed *first-degree*) are, by definition, injury confined to the epidermis. These injuries are painful, erythematous, and blanch to the touch with an intact epidermal barrier. Examples include sunburn or a very minor scald from a kitchen incident. These do not disrupt any underlying structures and therefore do not result in scarring. Treatment is aimed at comfort with the use of topical soothing salves and oral nonsteroidal antiinflammatory agents.

Partial-thickness burns (formerly called *second-degree*) are divided into two types: superficial and deep. All partial-thickness burns have some degree of dermal damage, and the division is based on the depth of injury into this structure. Superficial partial-thickness burns are limited to the papillary dermis and are erythematous, painful, blanch to touch, and often blister. Hair follicles remain viable and intact; thus, a finding on physical examination is retention of hairs to gentle pulling. Examples include scald injuries

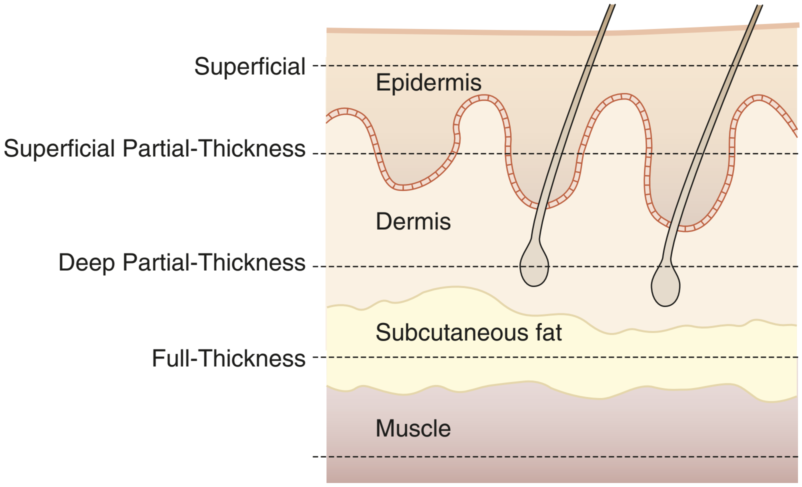

FIGURE 43.3 Depths of a burn. Superficial burns are confined to the epidermis. Superficial partial-thickness burns are limited to the epidermis and papillary dermis. Deep partial-thickness burns extend through the epidermis and reticular dermis. Full-thickness burns extend through the epidermis and dermis into subcutaneous fat and can involve injury to underlying tissue structures, such as muscle, tendons, and bone.

sustained in kitchen incidents and flash flame burns. These wounds spontaneously reepithelialize from retained epidermal structures in rete ridges and hair follicles in the follicular dermis in 7 to 14 days. After healing, these burns may have skin discoloration and textural differences without other significant scarring. Deep partial-thickness burns within the reticular dermis appear more pale and mottled, do not blanch to touch, and remain painful to pinprick. These burns heal in 15 to 21 days by reepithelialization from deep hair follicles and sweat gland keratinocytes, often with severe scarring as a result of loss of dermal integrity.

Full-thickness burns (formerly termed *third-degree*) extend through the epidermis and dermis into the underlying fat and are characterized by a hard leathery eschar that is painless and black, white, or cherry red in color depending on the temperature of the source and any associated Mailliard reaction. No epidermal or dermal keratinocytes remain; thus, these wounds must heal by reepithelialization from the wound edges. Deep dermal and full-thickness burns benefit from excision of the eschar with autologous skin grafting in order to heal in a timely fashion and to minimize contraction. Full-thickness burns can extend below the superficial fat to involve other structures, such as muscle and bone (formerly termed *fourth-degree*).

Currently, burn depth is most accurately assessed by judgment of experienced practitioners, although modern imaging technologies, such as laser Doppler flowmetry, laser speckle imaging, optical coherence, and multispectral imaging with or without artificial intelligence techniques hold the promise of improving assessment and guiding better treatment and outcomes.[8–10] Accurate assessment of depth is critical to determine optimal treatment for each affected area and ensure the best outcomes in terms of scarring and distress during treatment. Examination of the entire wound by surgeons ultimately responsible and accountable for management is the gold standard to guide treatment decisions. Imaging techniques and decision-support algorithms, some of which can be used sequentially, hold the promise to make such improvements.

Burn Size

Determination of burn size estimates the extent of injury. Burn size is traditionally assessed manually by the "rule of nines." In adults, each upper extremity and the head and neck are 9% of the TBSA, the lower extremities and the anterior and posterior trunk are 18% each, and the perineum and genitalia are assumed to be 1% of the TBSA (Fig. 43.4). Another method of estimating smaller burns is to equate the area of the open hand (including the palm and the extended fingers) of the patient as approximately 1% TBSA and then to transpose that measurement visually onto the wound for a determination of its size. This method is helpful when evaluating splash burns and other burns of disparate distribution.

Children have a relatively larger portion of the body surface area in the head and neck, which is compensated by a relatively smaller surface area in the lower extremities. Infants have 21% of the TBSA in the head and neck and 13% in each leg, which incrementally approaches adult proportions with increasing age. The Berkow formula is used to accurately determine burn size in children (Table 43.1).

SYSTEMIC CHANGES

Inflammation and Edema

Burns induce a massive increase in inflammation in response to injury in the wound first that is then generalized to all other tissues. The Glue Grant Investigators demonstrated that over 80% of the genes in circulating immune cells are radically changed after severe injury, including burns.[10] The changes involve most, if not all, cellular functions and pathways and was termed a *genomic storm*. This breadth and degree of change were not anticipated by the investigators, identifying that circulating leukocytes are radically activated in response to severe injury with dramatically increased expression of genes in the inflammatory, innate immunity, and antiinflammatory spheres. They also noted a significant downregulation of genes associated with adaptive immunity. Perhaps most interestingly, they found that later complications such as infection and organ failure were not related to tangible genomic changes during the course of recovery, differing only in the magnitude and duration of the initial changes. Persons with many types of injury were included in the study, but a large proportion of them had severe burns. The investigators further found no differences in the response by injury type; therefore, these findings are clearly applicable to burned patients. In particular, it is prudent to recognize that severe burns induce massive physiologic and immune changes that are prolonged for about a year after injury.[11] Further, tracking genomic and inflammatory mediator changes along the course of treatment is not likely to be fruitful to predict complications and infections because these are already established at the time of injury.[12]

Mediators that are produced locally induce vasoconstriction and vasodilation, increased capillary permeability, and edema. The whole body response then ensues based on the extent of injury, with changes in permeability and activity of mediators causing generalized edema through Starling forces in both burned and unburned skin. Initially, the interstitial hydrostatic pressures in the burned skin decrease dramatically with an associated slight increase in nonburned skin interstitial pressures. As plasma oncotic

pressures decrease and interstitial oncotic pressures increase, edema forms in the burned and nonburned tissues. The edema is greater in the burned tissues because of lower interstitial pressures.

Many mediators are proposed to account for changes in permeability after burns, including histamine, bradykinin, vasoactive amines, prostaglandins, leukotrienes, activated complement, and catecholamines, among others. Recently, investigators showed that shedding glycocalyx from plasma membranes is also instrumental in the process.[13] Mast cells in burned skin release histamine in large quantities immediately after injury, eliciting a characteristic response in venules by increasing intercellular junction space formation. The use of antihistamines in the treatment of burn edema, however, has had limited success. In addition, aggregated platelets release serotonin to play a major role in edema formation. This agent acts directly to increase pulmonary vascular resistance, and it indirectly aggravates the vasoconstrictive effects of various vasoactive amines. In addition, decreases in resuscitation fluid are seen with high-dose vitamin C therapy immediately after burns, presumably because of its antiinflammatory effects, although this has been questioned recently because the doses given are likely to have an independent osmotic diuretic effect.[14]

Microvascular changes induce cardiopulmonary alterations characterized by loss of plasma volume, increased peripheral vascular resistance, and subsequent decreased cardiac output immediately after injury. Studies in efforts to sustain intravascular volume by increasing oncotic pressure with colloid solutions, such as albumin, are currently underway. Cardiac output remains depressed from decreased blood volume and increased blood viscosity as well as decreased cardiac contractility. Ventricular dysfunction in this period is attributed to a circulating myocardial depressant factor present in lymphatic fluid, although the specific factor has never been isolated. Cardiac output is completely restored with resuscitation.[15]

Only over the past 10 years have we begun to understand the glycocalyx, its role in protecting against endotheliopathy, and that its breakdown in shock states contributes to extravascular fluid leak. The glycocalyx is a glycoprotein-polysaccharide matrix that serves as a barrier shielding the endothelium from direct blood flow, preventing vascular permeability, inhibiting coagulation, and deterring leukocyte adhesion.[16,17] Various shock and diseases states disrupt the glycocalyx, particularly a severe burn injury. Resuscitation with plasma may ameliorate this glycocalyx disruption, and research is ongoing.

Effects on the Renal System

Diminished blood volume and cardiac output result in decreased renal blood flow and glomerular filtration rate; this is mitigated somewhat by intravenous volume resuscitation. Other stress-induced hormones and mediators such as angiotensin, aldosterone, vasopressin, and thromboxane B_2 further reduce renal blood flow immediately after the injury. These effects result in oliguria, which, if left untreated, will cause acute tubular necrosis and renal failure. Before 1984, acute renal failure in burn injuries was almost always fatal. After 1984, however, techniques in intermittent dialysis became widely used to support the kidneys during recovery. Since that time, developments in continuous renal replacement therapies have radically changed outcomes related to renal failure in the severely burned. It was shown that 28-day mortality and in-hospital mortality in the severely burned with renal failure decreased by 50% and 25%, respectively, with the use of continuous venovenous hemofiltration compared with intermittent hemodialysis.[18] This is a massive improvement that has received significant attention corroborated by several other studies.[19]

Effects on the Immune System

Burns cause a global depression in immune function, which is demonstrated most prominently by prolonged allograft skin survival on burn wounds. As stated previously, after severe injury, adaptive immunity is downregulated in favor of innate immune mechanisms. Burned patients are then at great risk for a number of infectious complications, including bacterial wound infection, pneumonia, and fungal and viral infections. These susceptibilities and conditions are based on depressed cellular function in all parts of the immune system, including activation and activity of neutrophils, macrophages, T lymphocytes, and B lymphocytes. With burns of more than 20% TBSA, impairment of these immune functions is proportional to burn size.

Macrophage production after burns is relatively diminished, which is related to spontaneous elaboration of negative regulators of myeloid growth. This effect is enhanced by the presence of endotoxin and can be partially reversed with granulocyte colony-stimulating factor treatment or inhibition of prostaglandin E2.[20] Total neutrophil counts are initially increased after burn by demargination and decreased cell death by apoptosis. However, neutrophils that are present are dysfunctional in terms of diapedesis, chemotaxis, and phagocytosis; this is related to abnormalities in granulopoiesis and life span, cell trafficking, and antimicrobial effector functions. After 48 to 72 hours, neutrophil counts decrease somewhat like macrophages, with similar causes.

T-cell function is depressed after a severe burn. Until recently, T helper cells were categorized as Th1 and Th2 phenotypes, but this has been dramatically expanded to other phenotypes such as Th9, Th17, Th22, and T-regs; work on this categorization and relevant functions is ongoing. In particular, the Th17 phenotype is likely to play a significant role in the burn wound given its association with adaptive immunity on mucosal surfaces and the skin. This field continues to evolve as we examine the roles of each phenotype in response to antigens. Each is associated with typical cytokines, such as interleukin (IL)-2 for Th1 responses, IL-4 and IL-10 for Th2, and IL-17 and 22 for Th17. Burns also impair cytotoxic T-lymphocyte activity as a function of burn size, thus increasing the risk of infection, particularly from fungi and viruses. Early burn wound excision improves cytotoxic T-cell activity.[21]

Hypermetabolism

After severe burn and resuscitation, typically 3 to 4 days after injury, the condition of *hypermetabolism* develops, characterized by tachycardia, increased cardiac output, elevated energy expenditure, increased oxygen consumption, and massive proteolysis and lipolysis (Fig. 43.5). This response is seen in all major injuries but is present in its most dramatic form in severe burns. The condition is likely related to the massive inflammatory response already mentioned, but delivery of nutrition to support recovery from the wound and bed rest and immobility associated with treatment also plays a major, if not primary, role. Hypermetabolism may be sustained for months, leading to massive weight loss and decreased strength, particularly when muscle strength is needed to functionally recover from the injury. These changes in metabolic activity are caused in part by the release of catabolic hormones, such as catecholamines, glucocorticoids, and insulin/glucagon, among others. Catecholamines act directly and indirectly to increase glucose availability through hepatic gluconeogenesis and glycogenolysis and fatty acid availability through peripheral lipolysis. Effects are direct through α- and β-adrenergic receptors on myocytes, lipocytes, and hepatocytes. The indirect effects are mediated through stimulation of adrenergic receptors in endocrine tissue within the pancreas, which causes a relative increase in glucagon release compared with insulin. Normally, glucagon increases hepatic glucose production and peripheral lipolysis, whereas insulin has the opposite effects. Catecholamine stimulation of β-adrenergic receptors within the pancreas increases the release of both glucagon and insulin, but concurrent stimulation of α receptors has a greater inhibitory effect on insulin than on glucagon, resulting in a greater net release of glucagon. The effects of catecholamine-stimulated glucagon release then outweigh the

effects of insulin on glucose and fatty acid production and release. Glucocorticoid hormones, released by way of the hypothalamic-pituitary-adrenal axis, are mediated through neural stimulation. Cortisol has similar actions on energy substrates, and it induces insulin resistance, which is an additive to the hyperglycemia because of the release of liver glucose. Catecholamines, when combined with glucagon and cortisol, augment glucose release, which initially could be beneficial because glucose is the principal fuel of inflammatory cells and neural tissue.

Substrate supply for hepatic gluconeogenesis is produced through feeding (either enteral or parenteral), proteolysis of existing muscle tissue, and, to some extent, by peripheral lipolysis. Structural and constitutive proteins degraded to amino acids enter into (1) the tricarboxylic acid cycle for energy production, (2) the liver to be used as substrate for gluconeogenesis, or (3) the synthesis of acute-phase proteins. Lactate and alanine are important intermediates that are released in proportion to the extent of injury. Glutamine is also released in massive quantities, depleting muscle tissue stores to 50% of normal concentrations. After conversion to pyruvate or oxaloacetate, these amino acids form glucose with a net loss of adenosine triphosphate (ATP). Eighteen of the 20 amino acids are gluconeogenic. Increased acute-phase protein synthesis in the liver includes representative factors such as C-reactive protein, fibrinogen, α_2-macroglobulin, and complement. These are often used as proxies for the degree of hypermetabolism that is present, but, as discussed, the inflammatory response is so massive that most treatments will have little effect; perhaps the best strategy is to address the inflammatory condition of the wound through wound closure rather than untoward attention to the effects.

Peripheral lipolysis, mediated through the catabolic hormones, is another principal component of the metabolic response to severe burn. Elevation of catecholamines, glucagon, and cortisol levels stimulates the same or similar intracellular hormone-sensitive lipases in the adipocyte to release free fatty acids. These are circulated to the liver where they are oxidized for energy. However, the vast majority are reesterified to triglyceride and deposited in the liver or further packaged for transport to other tissues by way of very low-density lipoproteins. Glycerol from fat breakdown enters the gluconeogenic pathway at the glyceraldehyde 3-phosphate level after phosphorylation. In severely burned patients, the rates of lipolysis are dramatic, and the processing of lipid by the liver is often compromised from the increasing amounts of circulating fat. Adding fat in the diet only adds to the process. Fatty liver commonly develops, akin to nonalcoholic fatty liver disease, and is thought to be secondary to the overload of normal processing enzymes or perhaps to a downregulation of fatty acid handling mechanisms as a result of hormonal or cytokine changes associated with the injury.[22]

The classic description of the ebb and flow phases of response to illness and trauma deserve mention. The ebb phase is characterized by low metabolic rate, hypothermia, and low cardiac output. This is often temporally related to the onset of disease or time of injury. After resuscitation, this state gives way to the flow phase, which is characterized by high cardiac output and oxygen consumption, increased heat production, hyperglycemia, and an elevated metabolic rate. Moore classically defined these as the *catabolic* and *anabolic* portions of the flow phase of recovery.[23] Duration of the catabolic flow phase is also dependent on the type of injury and the efficacy of therapeutic interventions. The frequency and severity of complications also have a bearing on the length of time of this phase of recovery, which in critically ill patients can last for weeks or months. The anabolic flow phase is characterized by a slow reaccumulation of protein and fat that can extend for years after the injury.

INITIAL TREATMENT OF BURNS

Prehospital

During and immediately after injury, burned patients must be removed from the source and the burning process stopped. In the prehospital setting, this should be achieved first, but care must be taken that the rescuer does not become another victim. Universal precautions include wearing gloves and protective eyewear during retrieval. Burning clothing should be extinguished and removed as soon as possible to prevent further injury. Next attention should be directed at initial resuscitation, starting with the airway. For those burned with flames, inhalation injury should always be suspected and 100% oxygen given by facemask. All rings, watches, jewelry, and belts should be removed because they retain heat and can produce a tourniquet-like effect. Room-temperature water should be copiously poured on the wound for up to 30 minutes within 3 hours of injury to decrease the depth of the wound and improve healing and scarring.[24,25] Any subsequent measures to cool the wound should be avoided to preclude hypothermia during resuscitation. Patients should be rapidly transported to a local emergency department for initial stabilization; for those who meet the American Burn Association criteria for transfer to a burn center, timely arrangements should be made for transport.[26]

Initial Assessment

As with any injured patient, the initial assessment of a burn patient is divided into the primary and secondary survey. First, immediate life-threatening conditions are quickly identified and treated; in the secondary survey, a more thorough head-to-toe evaluation of the patient is undertaken.

Exposure to heated gases and smoke often results in damage to the upper respiratory tract. Direct injury to the upper airway results in localized edema, which, in combination with generalized whole body edema associated with severe burn, may obstruct the airway over the course of hours (not minutes). Airway injury must be suspected with facial burns, singed nasal hairs, carbonaceous sputum, and tachypnea, and respiratory status must be continually monitored to assess for airway intervention and ventilatory support. Progressive hoarseness is a sign of impending airway obstruction, and endotracheal intubation should be instituted before edema irretrievably distorts the upper airway anatomy. This is especially important in patients with massive burns, who may appear to breathe without problems early in the resuscitation period until several liters of volume are given to maintain homeostasis resulting in significant airway edema. In general, those with over 40% TBSA burns should be intubated early for this reason.

The chest should be exposed to assess breathing; airway patency alone does not ensure adequate ventilation. Chest expansion and equal breath sounds with carbon dioxide (CO_2) return from the endotracheal tube ensure adequate air exchange.

Blood pressure may be difficult to obtain in burned patients with edematous or charred extremities. Pulse rate can be used as an indirect measure of circulation; however, most burn patients remain tachycardic even with adequate resuscitation. For the primary survey of burned patients, the presence of pulses or Doppler signals in the distal extremities may be adequate to determine adequate circulation of blood until better monitors, such as arterial pressure measurements and urine output, can be established.

In those who have been in an explosion or deceleration incident, a possibility exists for spinal cord injury and other fractures. Appropriate cervical spine stabilization must be accomplished by whatever means necessary, including using cervical collars to keep the head immobilized until the condition can be evaluated and excluded.

Wound Care

Prehospital care of the burn wound is basic and simple. Protection from the environment with application of a clean dry dressing or sheet to cover the involved part is sufficient after the source has been controlled; damp dressings should not be used. Irrigation to cool the wound in the first 3 hours after injury might be considered in controlled conditions, but this should be done actively and not passively with dressings. Further, the patient should be wrapped in a blanket to minimize heat loss and for temperature control during transport. The first step in diminishing pain is to cover the wounds to prevent contact with exposed nerve endings. Intramuscular or subcutaneous narcotic injections for pain should never be used because drug absorption is decreased as a result of the peripheral vasoconstriction resulting in later and unexpected release with respiratory complications. Small doses of intravenous opioids may be given after complete assessment of the patient and after it is determined to be safe by an experienced practitioner.

Although prehospital management is simple, it is often difficult to accomplish appropriately, particularly in at-risk populations. Studies showed that initial burn first-aid treatment was inadequate in many patients.[24] These authors also showed that inadequate first-aid care was clearly associated with poorer outcomes. They suggested that defined education programs targeted to at-risk populations might improve these outcomes.

Transport

Rapid, uncontrolled transport of the burn victim is not a priority except when other life-threatening conditions coexist. In most incidents involving major burns, ground transportation of victims to the receiving hospital is appropriate, with air transport of greatest use when the distance from the incident and the hospital is 30 to 150 miles. For distances greater than 150 miles, transport by fixed-wing aircraft is most appropriate. Whatever the mode of transport, it should be of appropriate size and have emergency equipment available with trained personnel on board, such as a nurse, physician, paramedics, or respiratory therapists who are familiar with polytrauma patients.

Resuscitation

Formulas are used to estimate fluid volumes for resuscitation of a burned patient, all originating from classical experimental studies on the pathophysiology of burn shock (Table 43.2). Baxter established the basis for modern fluid resuscitation protocols,[27] showing that edema fluid in burn wounds is isotonic and contains the same amount of protein as plasma and that the greatest loss of fluid is into the interstitium. Baxter used various volumes of intravascular fluid to determine the optimal amount in terms of cardiac output and extracellular volume in a canine burn model, and this was applied to the clinical realm with the Parkland formula. Plasma volume changes were not related to the type of resuscitation fluid in the first 24 hours, but, thereafter, colloid solutions increased plasma volume by the amount infused. From these findings, the author concluded that colloid solutions should not be used in the first 24 hours until capillary permeability returned closer to normal.

TABLE 43.2 Resuscitation Formulas

FORMULA	CRYSTALLOID VOLUME
Parkland	4 cc/kg/% TBSA burned
Brooke	2 cc/kg/% TBSA burned
Galveston (pediatric)	5000 cc/m^2 burned + 1500 cc/m^2 total surface area

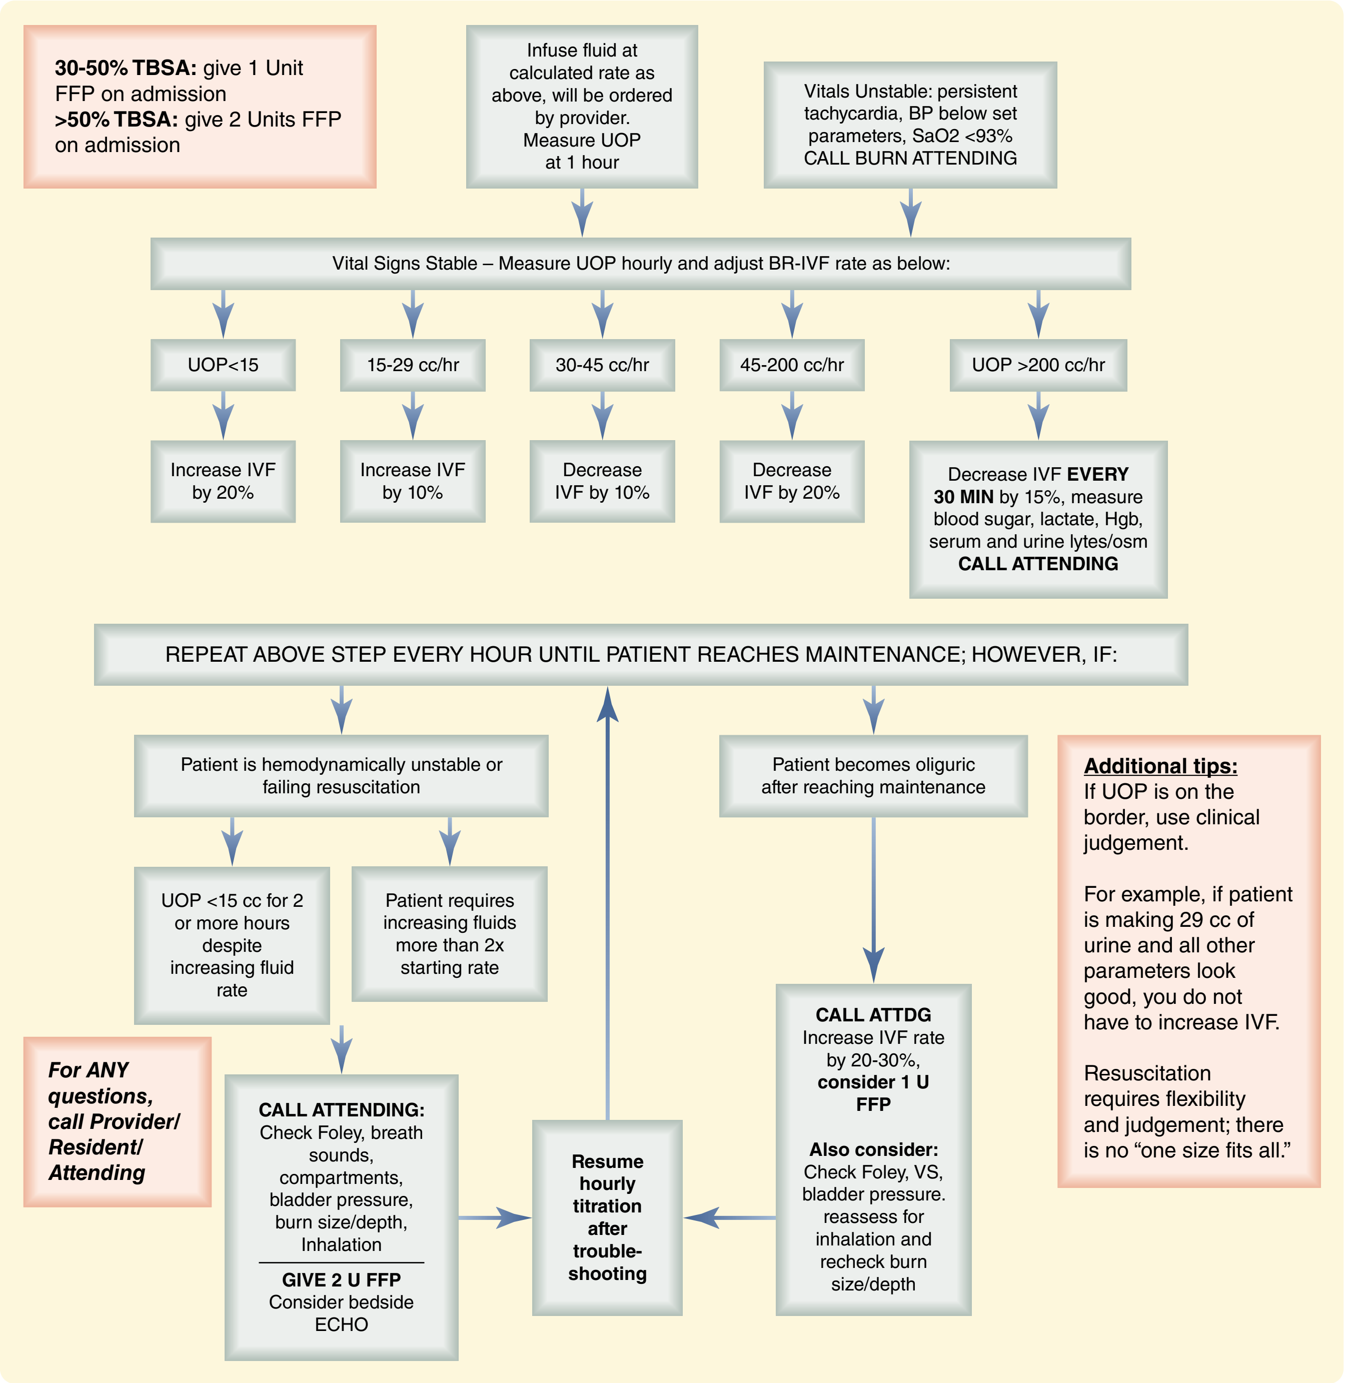
TBSA, Total body surface area.

Concurrently, Pruitt et al. showed the hemodynamic effects of fluid resuscitation in burns, which culminated in the Brooke formula.[28] They found that fluid resuscitation caused an obligatory 20% decrease in both extracellular fluid and plasma volume that concluded after 24 hours. In the second 24 hours, plasma volume returned to normal with the administration of colloid. Cardiac output was low in the first day despite resuscitation, but it subsequently increased to supernormal levels as the flow phase of hypermetabolism was established. Since these studies, investigators have found that much of the fluid needs are the result of "leaky" capillaries that permit passage of large molecules into the interstitial space, increasing extravascular colloid osmotic pressure. Intravascular volume follows the gradient to tissues, both into the burn wound and the nonburned tissues. Approximately 50% of fluid resuscitation given is sequestered in nonburned tissues in 50% TBSA burns.[29] Early resuscitation formulas such as the Evans and Brooke formulas aimed to administer 2 cc/kg/%TBSA, using colloid in the form of plasma. When plasma became unsafe (before the advent of modern viral screening), crystalloid and albumin became the mainstays of resuscitation. As a response to the changing paradigm, the original work done by Dr. Baxter was a crystalloid-only resuscitation, followed by an additional period of albumin after the 24-hour end point had been reached. When only lactated Ringer solution was given during the first 24 hours, most patients received 4 cc/kg/%TBSA to maintain urine output, and the Parkland formula became almost universally adopted and used for the next 40 to 50 years. When the use of colloid shifted from plasma products to simple albumin, it was thought to simply restore the oncotic gradient and also served as an antioxidant.

Recently, a small but growing body of convincing evidence suggests that administration of healthy plasma restores the damaged glycocalyx and reverses the capillary leak.[16,17] Despite advances in safety of blood products and some clinical studies circa 2000 showing reduction in resuscitation fluids, plasma was not universally readopted by the burn community. Crystalloid-based resuscitations, with some centers using rescue albumin, continue to be mainstream.

The term *fluid creep* was coined in 2000 by Basil Pruitt.[30] Literature from the 2000s demonstrated that patients were receiving almost twice the amount of fluids predicted by the Parkland formula, with the common development of complications such as abdominal compartment syndrome.[31] In the 2000s overresuscitation was a problem in many burn centers, and the etiology was multifactorial. Oversedation with opioids, surgeons moving to shift work and losing continuity of care, older patients with more comorbidities, higher incidence of obesity, and improved trauma systems allowed patients in more remote areas access to burn centers where some of the issues were implicated. Some of the patients previously considered nonsurvivable were now survivable and underwent challenging resuscitations. Since then, a concerted effort has ensued to safely reduce resuscitation fluids given.

The authors of this chapter currently use strategies to reduce fluid administration during burn shock. One author's burn center



30-50% TBSA: give 1 Unit FFP on admission
>50% TBSA: give 2 Units FFP on admission
Infuse fluid at calculated rate as above, will be ordered by provider. Measure UOP at 1 hour
Vitals Unstable: persistent tachycardia, BP below set parameters, SaO2 <93% CALL BURN ATTENDING
Vital Signs Stable – Measure UOP hourly and adjust BR-IVF rate as below:
UOP<15
15-29 cc/hr
30-45 cc/hr
45-200 cc/hr
UOP >200 cc/hr
Increase IVF by 20%
Increase IVF by 10%
Decrease IVF by 10%
Decrease IVF by 20%
Decrease IVF EVERY 30 MIN by 15%, measure blood sugar, lactate, Hgb, serum and urine lytes/osm CALL ATTENDING
REPEAT ABOVE STEP EVERY HOUR UNTIL PATIENT REACHES MAINTENANCE; HOWEVER, IF:
Patient is hemodynamically unstable or failing resuscitation
Patient becomes oliguric after reaching maintenance
Additional tips:
If UOP is on the border, use clinical judgement.
For example, if patient is making 29 cc of urine and all other parameters look good, you do not have to increase IVF.
Resuscitation requires flexibility and judgement; there is no “one size fits all.”
UOP <15 cc for 2 or more hours despite increasing fluid rate
Patient requires increasing fluids more than 2x starting rate
For ANY questions, call Provider/ Resident/ Attending
CALL ATTENDING: Check Foley, breath sounds, compartments, bladder pressure, burn size/depth, Inhalation
GIVE 2 U FFP Consider bedside ECHO
Resume hourly titration after trouble-shooting
CALL ATTDG Increase IVF rate by 20-30%, consider 1 U FFP
Also consider: Check Foley, VS, bladder pressure. reassess for inhalation and recheck burn size/depth

uses Burn Navigator, a computer algorithm–based decision support tool that has been shown in prospective studies to result in fluid administration of approximately 4 cc/kg/%TBSA.[32] This program has the advantage of assisting the less experienced provider who may not be as comfortable with a complex resuscitation as a career burn surgeon. The other author uses early plasma administration to address capillary leak for adjusted ideal body weight index instead of actual weight, with the addition of more plasma as indicated by clinical response. The adjusted ideal body weight index is a third of the difference between the ideal and actual body weight—an equation used to dose hydrophilic medications for obese patients receiving dialysis. The concept of resuscitating an overweight burn patient is similar, as adipose tissue does not contain the vascular supply or water content of lean tissue. In this protocol (Fig. 43.6), those with >30% TBSA receive plasma on admission and if oliguric for 2 consecutive hours during resuscitation. Initially, patients were started at 2 cc/kg/%TBSA, increasing to 3 cc/kg/%TBSA for those with extensive deep injuries *or* inhalation injury and 4 cc/kg/%TBSA if they had *both* inhalation and third-degree burns. This approach resulted in

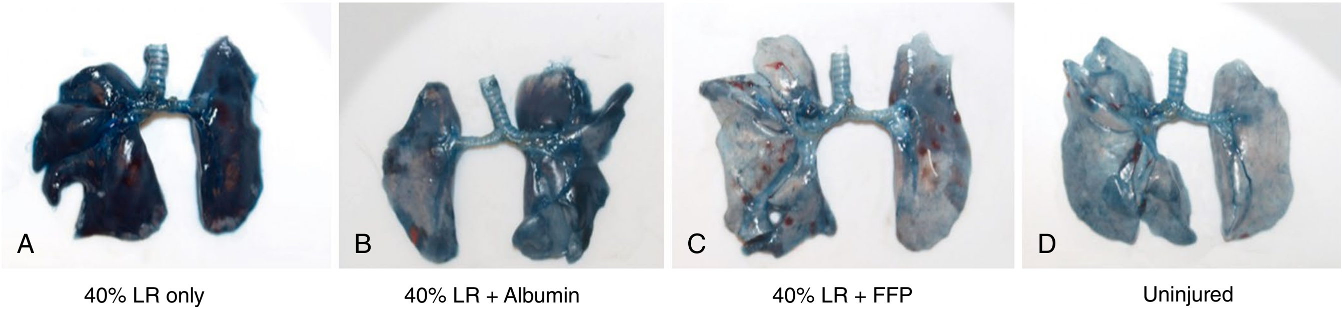

FIGURE 43.7 Lungs in severely burned animals treated with lactated Ringer *(LR)* alone (A), LR with albumin (B), and LR with fresh frozen plasma (C). Uninjured lungs are controls (D). Blue coloration is from capillary leakage of dye injected during resuscitation.

reduction of fluid volumes from 4.1 to 3.3 cc/kg/%TBSA in a single burn center accompanied by significant improvements in mortality, ventilator-free days, acute kidney injury (AKI), tracheostomy, and dialysis.[33] Fluid administration was further reduced in an updated version that aimed to start almost everyone at 2 cc/kg/%TBSA unless high-grade inhalation and mostly full-thickness burn were present; the most severely injured patients are started at a rate corresponding to 3 cc/kg/%TBSA. This algorithm has resulted in a reduction of median fluid administration to 1.7 cc/kg/%TBSA, with a median of 30 ventilator-free days and an observed to expected length of stay ratio of 0.4, without an increase in mortality or significant AKI compared with the first publication.[34]

Shupp et al. elucidated the details of the mechanism of plasma utility in burn resuscitation in rodent models.[16] In Fig. 43.7, photos of a rat lung explant model depict Evans blue dye extravasation after burn injury as a marker of endotheliopathy. When glycocalyx is damaged and capillary permeability increases, blue dye extravasates in addition to other fluids. The blue staining and endotheliopathy were most striking in resuscitation with lactated Ringer alone, with the lungs completely blue. With crystalloid and colloid, a slight attenuation of the blue dye leakage and staining was found. In contrast, the appearance of the lungs treated with crystalloid and plasma have a marked improvement, very close in appearance to the uninjured lungs. This study also demonstrated a significant reduction in edema per gram of tissue when plasma was added to crystalloid, whereas the small reduction with the addition of albumin was not statistically significant. Serum markers of endotheliopathy such as SCD-1 were significantly increased in injured animals compared with controls, but plasma significantly attenuated SCD-1 levels.

Use of the Parkland and modified Brooke formulas remains within the standard of care; however, current evidence suggests reexamination. Inexperienced providers often take the formula and its application as rote, particularly the point in that it is used to calculate a starting fluid rate, which then must be titrated up or down on an hourly basis. This dynamic process demands the provider match the fluids with the evolving capillary leak over time, which often differs based on patient and injury characteristics. The best marker of a successful resuscitation is urine output. Traditional metrics tout 30 cc/h as adequate for most adults or, alternatively, 0.5 cc/kg/h, and 1 cc/kg/h for children. In analyzing the area under the curve of a Parkland formula resuscitation (fluid administered over time), most patients receive approximately half of the total 4 cc/kg/%TBSA in the first 8 hours (Fig. 43.8). The two rectangles are equivalent size and approximate the total area under the curve. Hence, one approach is to divide the estimated total fluid over 24 hours (4 cc/kg/%TBSA) by 8 and then by 2, with half in the first 8 hours. Dividing the total 24-hour volume calculation by 16 eliminates a step to obtain the starting hourly fluid rate. Another approach is the "Rule of Tens," multiplying TBSA burned times 10 as an initial rate.[35] The same general concept should be used in applying the consensus formula with 2 or 3 cc/kg/%TBSA, then divide by 16 to calculate the starting fluid rate. This is usually necessary only for patients with 20% TBSA or greater, as smaller injuries rarely develop burn shock or a clinically significant endotheliopathy.

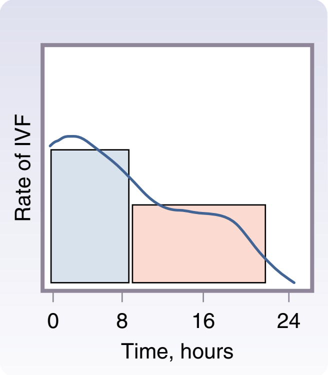

FIGURE 43.8 Typical declines in intravenous fluid administration during burn resuscitation. Colored boxes represent Parkland formula calculations, and the line represents the typical dynamics of a closely monitored resuscitation. *IVF,* Intravenous fluid.

Adequate resuscitation of the burned patient involves establishing and maintaining reliable intravenous access. Increased times to beginning resuscitation of burned patients result in poorer outcomes, and delays should be minimized. Venous access is best attained through short peripheral catheters in unburned skin; however, veins in burned skin can be used and are preferable to no intravenous access. Superficial veins are often thrombosed in full-thickness injuries and are therefore not suitable for cannulation. Saphenous vein cut-downs are useful in cases of difficult access and are used in preference to central vein cannulation because of lower complication rates. Modern techniques with ultrasound imaging of veins have made this practice rare. In children younger than 6 years of age, experienced practitioners can use intramedullary (i.e., intraosseous) access in the proximal tibia until intravenous access is accomplished. Lactated Ringer solution without dextrose is the fluid of choice except in children younger than 2 years, who should receive 5% dextrose and lactated Ringer.

For burned children, formulas are commonly used that account for changes in surface area to mass ratios and baseline insensible losses. The Galveston formula recommends 5000 mL/m^2 per TBSA burn in m^2 + 1500 mL/m^2 TBSA for maintenance in the first 24 hours to account for resuscitation volumes and maintenance needs. All the formulas listed in Table 43.2 calculate recommendations for the amount of volume given in the first 24 hours after injury (not arrival to the hospital), one half of which is to be given in the first 8 hours after injury. Ongoing monitoring and adjustment are indicated.

Hypertonic saline solutions have theoretical advantages in burn resuscitation. These solutions are purported to decrease net fluid intake, decrease edema, and increase lymph flow, probably by the transfer of volume from the intracellular space to the interstitium. When using these solutions, severe hypernatremia must be avoided, and it is recommended that serum sodium concentrations not exceed 160 mEq/dL. However, it must be noted that patients with more than 20% TBSA burns who were randomized to either hypertonic saline or lactated Ringer solution resuscitation did not have significant differences in volume infused or changes in percent weight gain.[36] Other investigators also found an increase in renal failure with hypertonic solutions that has tempered further efforts in this area of investigation.[37] Many of these studies are quite dated, but the use of hypertonic saline does not appear to have entered the marketplace with any enthusiasm. Currently, we cannot recommend its widespread use unless new data emerge in its favor.

To combat any complications of aspiration, a nasogastric tube should be inserted in all patients with major burns. This is especially important for all patients being transported in aircraft at high altitudes. Additionally, all patients should be restricted from taking anything by mouth until the transfer has been completed. Decompression of the stomach is usually indicated because the apprehensive patient will swallow considerable amounts of air and distend the stomach.

Recommendations for tetanus prophylaxis are based on the condition of the wound and the patient's immunization history. All patients with burns greater than 10% TBSA should receive 0.5 mL tetanus toxoid. If prior immunization is absent or unclear, or the last booster dose was more than 10 years ago, 250 units of tetanus immunoglobulin is also given.

Escharotomies

When deep partial-thickness or full-thickness burns encompass the circumference of an extremity, peripheral circulation to the limb can be compromised. Development of generalized edema beneath a nonyielding eschar impedes venous outflow and eventually affects arterial inflow to the distal beds. This is recognized by numbness and tingling in the limb and increased pain in the digits. Arterial flow can be assessed by determination of Doppler signals in the digital arteries and the palmar and plantar arches in affected extremities; capillary refill and compartment pressures can also be assessed. Extremities at risk are identified either on clinical examination or on measurement of tissue pressures greater than 30 mm Hg. These extremities should undergo escharotomy, which releases the burn eschar only. This procedure is generally performed at the bedside by incising the lateral and medial aspects of the extremity with a scalpel or electrocautery unit. The entire constricting eschar must be incised longitudinally to completely relieve impediment to venous blood flow. For the upper extremities, incisions are carried down onto the thenar and hypothenar eminences if indicated. Distensible tissues in the fingers is minimal; therefore, finger escharotomies are not indicated during resuscitation in the absence of clear signs of ischemia (Fig. 43.9). If it is clear that the wound will undergo excision and grafting because of its depth, escharotomies are safest to restore perfusion to the underlying nonburned tissues until formal excision. If vascular compromise has been prolonged, reperfusion after an escharotomy may cause reactive hyperemia and further edema formation in the muscle, making continued surveillance of the distal extremities necessary. Increased muscle compartment pressures after escharotomies may then indicate fasciotomies if pressures are not released with escharotomy. The most common complications associated with these procedures are blood loss and the release of anaerobic metabolites, causing transient hypotension. If distal perfusion does not improve with these measures, central hypotension from hypovolemia should be suspected and treated.

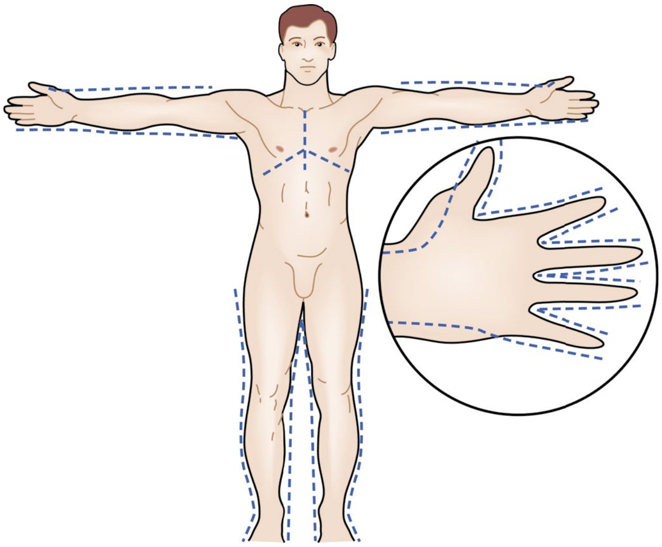

FIGURE 43.9 Recommended location for escharotomies. In limbs with escharotomies indicated, the incisions are made on the medial and lateral sides of the extremity through the eschar. In the case of the hand, incisions are made on the dorsum of the hand and thenar and hypothenar eminences.

A constricting truncal eschar can cause a similar phenomenon, except the effect is to decrease ventilation by limiting chest excursion. Any acute decrease in ventilation in a burn patient should produce inspection of the chest with appropriate escharotomies to relieve the constriction and allow adequate tidal volumes. This becomes evident for patients whose peak airway pressures increase.

Inhalation Injury

One major factor contributing to death in severe burns is the presence of inhalation injury. Smoke damage adds another inflammatory focus and impedes normal airway function for critically injured patients. Inhalation injury increases the amount of time spent on mechanical ventilation, a strong predictor of mortality. Early diagnosis and prevention of complications are of interest to decrease morbidity and mortality rates related to this condition.

With inhalation injury, damage is primarily from chemical burns associated with inhaled toxins. Heat is dispersed in the upper airways, whereas the cooled particles of smoke and toxins are carried distally into the major airways principally, and occasionally to the lower airways and the alveoli depending on the type of smoke and duration of exposure. Direct thermal damage to the lung is rarely seen because of dispersal of the heat in the pharynx. The exception is high-pressure steam inhalation, which has 4000 times the heat-carrying capacity of dry air.

The response of the airways to smoke inhalation is an immediate dramatic increase in blood flow from the bronchial arteries with edema formation and increased lung lymph flow. The lung lymph in this situation is similar to serum, indicating that permeability at the capillary level is markedly increased. The edema that results is associated with an increase in lung neutrophils, and it is postulated that these cells may be the primary mediators of pulmonary damage with this injury. Neutrophils release proteases and oxygen free radicals to produce conjugated dienes by lipid peroxidation. High concentrations are present in the lung lymph and pulmonary tissues after inhalation injury, suggesting that the increased concentration of neutrophils is active in producing cytotoxic materials. When neutrophils are depleted before injury by nitrogen mustard, increases in lung lymph flow and conjugated diene levels are markedly reduced.[38]

Another hallmark of inhalation injury is separation of the ciliated epithelial cells from the basement membrane followed by exudate formation within the airways. The exudate consists of proteins found in the lung lymph, and, eventually, it coalesces to form fibrin casts. Clinically, these fibrin casts can be difficult to clear with standard airway suction techniques. These casts also add distal barotrauma to localized areas of lung by forming a ball valve that is open with inspiration/airway dilatation and closes during expiration; the additional volume of air adds pressure that is associated with numerous complications, including pneumothorax and decreased lung compliance.

Smoke inhalation is commonly associated with a clinical history of closed-space smoke exposure, hoarseness, wheezing, and carbonaceous sputum. It may also be associated with facial burns and singed nasal hairs. Each of these findings individually has poor sensitivity and specificity; therefore, the definitive diagnosis should be further clarified by the use of bronchoscopy. Bronchoscopy reveals early inflammatory changes such as erythema, ulceration, and prominent vasculature in addition to infraglottic soot. The findings of airway erythema and ulceration alone are also nonspecific, and these findings must be placed with the entire clinical presentation to verify significant inhalation injury. Initial treatment for severe inhalation injury is institution of mechanical ventilation for airway management and lung support to maintain gas exchange. Repeated bronchoscopy often reveals continued ulceration of the airways with granulation tissue formation, exudate formation, inspissation of secretions, and focal edema. Eventually, the airway heals by replacement of the sloughed cuboidal ciliated epithelium with squamous cells and scar.

Combustion products of organic and inorganic materials found in smoke cause direct damage to the airway cells, but also have significant systemic effects. Most notably, carbon monoxide (CO) and hydrogen cyanide (HCN) can cause physiologic derangements that can lead to death if not recognized and treated appropriately. CO exposure should be presumed in all cases of suspected inhalation injury. It is impossible to detect without special equipment because of its properties of being colorless, odorless, tasteless, and nonirritating. Once inhaled, CO rapidly crosses the pulmonary capillary membrane and binds to hemoglobin with approximately 200 times the affinity of oxygen, forming carboxyhemoglobin. CO also causes a conformational change to hemoglobin that diminishes oxygen off-loading ability in peripheral tissues (left-shift in the hemoglobin dissociation curve). Oxygen delivery is further impaired by hypoxia-induced cardiac dysfunction. Intracellularly, CO also has been shown to bind cytochrome c oxidase, disrupting the electron transport chain in mitochondria, resulting in a functional shift from aerobic to anaerobic metabolism and worsening oxidative stress. The impact of CO is most apparent in organ systems with high metabolic output such as the brain and heart; CO poisoning therefore most commonly manifests as neurologic changes such as dizziness or altered mental status and cardiovascular findings such as arrhythmias and even infarction.

Widespread use of synthetic materials in construction and home furnishings has led to production of increased levels of HCN gas during house fires. Cyanide is a potent and rapidly acting poison, which, under normal conditions, is converted into thiocyanide that is excreted through the urine. This system is easily overwhelmed in the setting of inhalation injury, leading to accumulation of circulating cyanide ions. The cyanide ion interferes with cellular energy production, leading to rapid depletion of ATP stores and the subsequent development of lactic acidosis. These events aside, debate exists as to whether HCN is truly a significant contributor to inhalation injury, in large part because of the fact that HCN has a low flash point and is therefore rapidly oxidized by the fire, thus limiting exposure. Unfortunately, the unpredictable nature of the gaseous compounds iteratively generated and consumed during a fire limits ability to study subsequent effects both systemically and as a direct pulmonary irritant.

CO poisoning is measured by carboxyhemoglobin levels, with elevations above 5% considered to have toxicity ramifications. Headaches are generally present with levels above 10%, dizziness and impaired judgment at 20%, dyspnea above 30%, and syncope, seizures, and obtundation over 40%. Initial treatment is 100% oxygen to decrease the half-life of carboxyhemoglobin from 4 hours on room air to 1 hour. For extreme conditions, hyperbaric oxygen might be considered. For cyanide toxicity, removal from the source is indicated, and hydroxocobalamin might be given intravenously; this will result in orange coloration of the urine.

The clinical course of patients with inhalation injury is divided into three stages. The first is acute pulmonary insufficiency. Patients with severe lung injuries begin to show signs of pulmonary failure from the time of injury with asphyxia, CO poisoning, bronchospasm, and upper airway obstruction. Clinical signs of parenchymal damage with hypoxia are not common during this phase. The second stage occurs from 72 to 96 hours after injury and is associated with increased extravascular lung water, hypoxia, and development of diffuse lobar infiltrates. This condition is similar clinically to adult respiratory distress syndrome (ARDS) occurring in nonburned injured and critically ill patients. In the third stage, clinical bronchopneumonia dominates and appears in up to 60% of these patients. These infections generally occur 3 to 10 days after burn injury and are associated with the expectoration of large mucous casts formed in the tracheobronchial tree. The differentiation of pneumonia from tracheobronchitis is difficult at this stage, and bronchoscopy with lavage may be of assistance. Early pneumonias are usually caused by penicillin-resistant *Staphylococcus* species, whereas after 5 to 7 days, the changing flora of the burn wound is reflected in the appearance in the lung of gram-negative species, especially *Pseudomonas* and *Klebsiella*. Ball-valve effects and ventilator-associated barotrauma are also hallmarks of this period.

Management of inhalation injury is directed at maintaining open airways and maximizing gas exchange while the lung heals. A coughing patient with a patent airway can clear secretions much more effectively than any suctioning technique (including bronchoscopy), and efforts should be made to manage patients without mechanical ventilation if possible. If respiratory failure is imminent, intubation should be instituted, with frequent chest physiotherapy and suctioning performed to maintain pulmonary toilet. Frequent bronchoscopy may be indicated to clear inspissated secretions. Mechanical ventilation should be used to provide gas exchange with as little barotrauma as possible using permissive hypercapnia and ARDS ventilation protocols. Arterial oxygen tensions of greater than 60 (or an oxygen saturation of 92%) are also tolerated to minimize oxygen toxicity to the lungs. When the clinical condition improves to the point of weaning from ventilatory support, oxygen concentration, positive end-expiratory pressure, and ventilator volumes and rate should be decreased in a graduated manner until the patient can be extubated. This may take several weeks.

Inhalation treatments have been effective in improving the clearance of tracheobronchial secretions and decreasing bronchospasm (Table 43.3). Intravenous heparin has been shown to reduce tracheobronchial cast formation, minute ventilation, and peak inspiratory pressures after smoke inhalation.[39] When heparin was administered directly to the lungs in a nebulized form, it had similar effects on casts without causing systemic coagulopathy. When N-acetylcysteine treatments are added to nebulized heparin in burned children with inhalation injury, reintubation rates and mortality rates are decreased.[40] In addition to the measures already discussed, adequate humidification and treatment of bronchospasm with β-agonists are indicated. Steroids are not of benefit in inhalation injury and should not be given unless the patient is steroid dependent before injury or if the patient has bronchospasm resistant to standard therapy. Other potential treatments are hypertonic saline to induce coughing and racemic epinephrine to reduce mucosal edema for those who are extubated.

In addition to conventional ventilator methods, novel ventilator therapies have been devised to minimize barotrauma, including high-frequency percussive ventilation. This method combines standard tidal volumes and respirations (ventilator rates 6–20/minute) with smaller high-frequency respirations (200–500/minute) and permits adequate ventilation and oxygenation in patients who failed conventional ventilation. One reason for the greater utility of this method is that it recruits alveoli at lower airway pressures. This ventilator method may also have a percussive effect that loosens inspissated secretions and improves the pulmonary toilet, although the percussive effects can lead to additional airway injury.[39]

Several clinical studies showed pulmonary edema is not prevented by fluid restriction. Indeed, fluid resuscitation appropriate for the patient's other needs results in a decrease in lung water, has no adverse effect on pulmonary histology, and improves survival rate. Although overhydration can increase pulmonary edema, inadequate hydration increases the severity of pulmonary injury by sequestration of neutrophils, leading to increased risk of death. In both animal and clinical studies, resuscitation was adequate if normal cardiac index or urine output was maintained.

Prophylactic antibiotics for inhalation injury are not indicated but are clearly to be used for diagnosed lung infections. Empirical choices for treatment of pneumonia before culture results are returned should include coverage of methicillin-resistant *Staphylococcus aureus* and gram-negative organisms (especially *Pseudomonas*).

As patients recover from lung injury, extubation should ensue as soon as possible. Patients are able to clear their own airways through coughing more effectively than suction through an endotracheal tube. This is preferably done as soon as upper airway edema has resolved (injury day 1–2) in those who were intubated to control the airway or for burn excision. It is our experience that patients who are extubated with the same degree of inhalation injury do better than those who are intubated. Standard extubation criteria can be used, although many patients who do not meet these criteria may also do well without mechanical ventilation. If the airway is easily accessible by airway experts, a trial of extubation might be of benefit in patients with borderline weaning parameters.

TABLE 43.3 **Inhalation Treatments of Smoke Inhalation Injury**

TREATMENT	TIME AND DOSE
Bronchodilators (e.g., albuterol)	q2h
Nebulized heparin	5000–10,000 units in 3 cc normal saline q4h
Nebulized acetylcysteine	20%, 3 cc q4h

q2h, Every 2 hours; *q4h*, every 4 hours.

Wound Care

After the airway is assessed, other injuries are addressed, and resuscitation is underway, attention must be turned to the burn wound. Treatment depends on the characteristics and size of the wound, with all treatments aimed at rapid and less painful healing. Current therapy directed specifically toward burn wounds can be divided into three stages: assessment, management, and rehabilitation. Once the extent and depth of the wounds have been assessed and the wounds thoroughly cleaned and debrided, the management phase begins. Each wound should be dressed initially with an appropriate covering that serves several functions. First, it should protect the damaged epithelium, minimize bacterial and fungal colonization, and provide splinting action to maintain the desired position of function. Second, the dressing should be reasonably occlusive to reduce evaporative heat loss and minimize cold stress. Third, the dressing should provide comfort over the painful wound.

The management of a very deep or very superficial burn wound is relatively straightforward. A large third-degree burn will likely benefit from excision of the burn eschar and wound closure with skin grafts or local flaps, if available, after initial treatment. The clearly superficial burn will heal with almost any reasonable wound care strategy (described later). The challenge in decision-making lies in management of the indeterminate burn, where a significant depth of the dermis is injured with uncertainty regarding whether it will heal spontaneously in a timely fashion without increased risk of infection. Some providers allow a period for these indeterminate-depth wounds to "declare," involving painful dressing changes, increased hospital stay, and protracted time to reintegration. As another confounder, topical antibiotic use during this period often obfuscates the wound appearance by formation of pseudoeschar, making the wound appear to be deeper than it is. Thus, treatment of burn-injured patients absolutely requires accurate wound assessment to determine appropriate interventions. Strategies are further complicated by the fact that clinical assessment of these challenging middle to deep partial-thickness burn depths, even by experts in the field, has an accuracy of only 60% to 80%. A recent study demonstrated 73% accuracy from a group of multidisciplinary burn experts in predicting whether a burn wound would be nonhealing and would ultimately receive a skin graft.[41]

Improving indeterminate burn wound assessment performance optimizes the use of limited resources in burn care by accurately determining wound depth with immediate implementation of timely strategies. Several older technologies designed to aid in burn depth assessment exist, but they are not the standard of care in the United States. These technologies include but are not limited to laser Doppler imaging (LDI), laser speckle imaging, thermography, video-microscopy, optical coherence, and spatial frequency domain imaging.[9] Many of these technologies can be used in conjunction with artificial intelligence (AI), and LDI is the most highly validated, but they all have significant limitations.

Some newer promising technologies have recently been developed. Preliminary data suggest that an experimental device (DeepView Wound Imaging System, Spectral MD, Dallas, TX) using multispectral imaging combined with a convolutional neural network AI architecture may be more accurate than experienced burn providers in predicting nonhealing of burns. Early proof-of-concept data demonstrate a $>90\%$ accuracy and improved specificity, sensitivity, positive predictive value, and negative predictive values.[10] However, the device is not yet commercially available as of 2025.

Another novel method of accurate burn depth estimation is immediate enzymatic excision of burn wounds with bromelain (Nexobrid, Mediwound Ltd., Yavne, Israel). This technology removes eschar while preserving healthy dermis, allowing the provider to directly visualize and firmly assess depth of dermal injury previously obscured by eschar. Preliminary data suggest that this method results in chemical escharotomy and direct assessment of residual dermis 2.8 to 5.9 days sooner than standard of care. With early visualization and dermal preservation, patients treated with bromelain also undergo less autografting. This product was FDA approved in 2023.[42] The authors also currently use other technologies for a more selective surgical excision including the circular dermatome, dermabrasion, and water jet scalpel (Versajet, Smith & Nephew, Watford, England).

The choice of initial dressing is based on the characteristics of the treated wound. Superficial epidermal wounds are minor, with minimal loss of barrier function; thus, no dressing is indicated, with treatment by topical salves to keep the skin moist. Systemic nonsteroidal antiinflammatory agents given by mouth assist in pain control. Partial-thickness wounds are treated with daily or every-other-day dressing changes with topical antibiotics, cotton gauze, and elastic wraps or with one of the longer-lasting silicone or cloth dressings containing silver as an antimicrobial. Alternatively, the wounds can be treated with a temporary biologic or synthetic covering to close the wound that may or may not be applied in the operating room (Table 43.4). Identified deep partial-thickness or full-thickness wounds benefit from excision and grafting for sizable burns (i.e., >5 cm^2), and the choice of initial dressing should be aimed at holding bacterial proliferation in check and providing occlusion until the operation is performed.

TABLE 43.4 Biologic Coverings

Xenograft	Occlusive closure of the wound, some immunologic benefits
Allograft	Occlusive closure of the wound, provides normal functions of skin, dermal elements can engraft and worsen scarring
Suprathel	Occlusive closure of the wound, decreased pH inhibiting microbial growth
StrataGraft	Occlusive closure of the wound, active allogeneic cells inhibiting infection

Antimicrobials

The timely and effective use of antimicrobials has revolutionized burn care by decreasing invasive wound infections. The untreated burn wound rapidly becomes colonized with bacteria and fungi with loss of innate skin barrier mechanisms. As the organisms proliferate to high wound counts ($>10^5$ organisms per gram of tissue), some may penetrate into viable tissue. Organisms then invade blood vessels, causing a systemic infection that often leads to the death of the patient. This scenario has become uncommon in most burn units because of the effective use of antibiotics and wound care techniques. The antimicrobials that are used can be divided into those given topically and systemically.

Available topical antibiotics can be divided into three classes: salves, soaks, and antimicrobial dressings. Salves are generally applied directly to the wound with cotton dressings placed over them (Table 43.5); soaks are solutions poured into cotton dressings on the wound; and antimicrobial dressings contain active agents to inhibit microbial growth, generally some form of silver ion or other antibiotic. Each of these classes of antimicrobials has advantages and disadvantages. Salves may be applied daily but may lose their effectiveness between dressing changes. Frequent dressing changes can result in shearing with loss of grafts or underlying healing cells as well as procedural pain. Soaks remain effective because antibiotic solution can be added without removing the dressing; however, the underlying skin can become macerated. Longer-term antimicrobial dressings have the advantage of less frequent painful changes, decreasing both pain and provider effort, but some of these must remain moist and thus must be monitored.

Topical antibiotic salves include 11% mafenide acetate (Sulfamylon), 1% silver sulfadiazine (Silvadene), polymyxin B, neomycin, bacitracin, mupirocin, and the antifungal agent nystatin, among others. No single agent is completely effective, and each has advantages and disadvantages. Silver sulfadiazine was commonly used before the development of newer antimicrobial dressings. It has a broad spectrum of activity because its silver and sulfa moieties are effective against gram-positive, most gram-negative, and some fungal forms. Some *Pseudomonas* species possess plasmid-mediated resistance. Silver sulfadiazine is relatively painless upon application, has high patient acceptance, and is easy to use. However, it must be changed daily, which induces significant repeated painful episodes. Occasionally, patients complain of a burning sensation after it is applied, and, in a few patients, a transient leukopenia develops 3 to 5 days after its continued use. This leukopenia is generally harmless and resolves with or without treatment cessation. Of some concern is the finding of wound healing inhibition by the agent.

Mafenide acetate is another topical agent with a broad spectrum of activity owing to its sulfa moiety. It is particularly useful against resistant *Pseudomonas* and *Enterococcus* species. It also penetrates eschar, which silver sulfadiazine does not. Disadvantages include painful application on skin, such as in second-degree wounds. It also can cause an allergic skin rash, and it has carbonic anhydrase inhibitory characteristics that can result in a metabolic acidosis when applied over large surfaces. For these reasons, mafenide sulfate is typically reserved for small full-thickness injuries.

Petroleum-based antimicrobial ointments with polymyxin B, neomycin, and bacitracin are clear on application, painless, and allow for easy wound observation. These agents are commonly used for treatment of facial burns, graft sites, healing donor sites, and small partial-thickness burns. Mupirocin is a petroleum-based ointment that has improved activity against gram-positive

TABLE 43.5 **Burn Wound Dressings**

DRESSING	ADVANTAGES AND DISADVANTAGES
Salves	
Silver sulfadiazine	Broad spectrum, painful daily dressing changes, does not penetrate eschar, inhibition of epithelialization
Mafenide acetate 8.5%	Broad spectrum, penetrates eschar, painful application to partial-thickness burns, painful daily dressing changes, potential for metabolic acidosis, inhibition of epithelialization
Bacitracin	Gram-positive coverage, painful daily dressing changes
Neomycin	Gram-positive coverage, painful daily dressing changes
Bactroban	Gram-positive coverage, painful daily dressing changes
Polymyxin B	Gram-negative coverage, painful daily dressing changes
Nystatin	Fungal coverage, cannot be used in combination with mafenide acetate
Solutions	
Silver nitrate 0.5%	Effective against all microbes, stains contacted areas, associated with methemoglobinemia
5% Mafenide acetate	Broad spectrum, penetrates eschar, painful application to partial-thickness burns, painful daily dressing changes, potential for metabolic acidosis, inhibition of epithelialization
Dakin's solution	0.5% sodium hypochlorite with buffers, effective against all microbes, inhibits epithelialization
Domboro solution	0.25% acetic acid with buffers, effective against most microbes particularly *Pseudomonas,* inhibits biofilm formation
Antimicrobial Dressings	
Silver-containing dressings	Broad spectrum, long-term use minimizing painful wound care, does not penetrate eschar, difficult to assess the wound

bacteria, particularly methicillin-resistant *S. aureus* and selected gram-negative bacteria. Nystatin, either in a salve or powder form, can be applied to wounds to control fungal growth. Nystatin-containing ointments can be combined with other topical agents to decrease colonization of both bacteria and fungus.

Available agents for application as a soak include 0.5% silver nitrate solution, 0.05% Dakin (sodium hypochlorite with buffers), and 0.25% Domboro (acetic acid with buffers). Mafenide acetate 5% solution was previously available but has been removed from the marketplace to the detriment of burned patients and providers. Silver nitrate has the advantage of being painless on application and having complete antimicrobial effectiveness. The disadvantages include its staining of surfaces to a dull gray or black when the solution dries. This can become problematic in deciphering wound depth during burn excisions and in keeping the patient and their surroundings clean of the black staining. The solution is hypotonic as well, and continuous use can cause electrolyte leaching, with rare methemoglobinemia as another complication. Dakin's solution, which is a dilute solution of sodium hypochlorite with added buffering agents, has effectiveness against most microbes; however, it also has cytotoxic effects on the healing cells of patients' wounds. Low concentrations of sodium hypochlorite have less cytotoxic effects while maintaining most of the antimicrobial effects. Hypochlorite ion is inactivated by contact with protein, so the solution must be continually changed. A similar compound is available to be used in the same way with hypochlorous ion rather than hypochlorite (Vashe). The same is true for acetic acid solutions, which may be more effective against *Pseudomonas*. Mafenide acetate soaks have the same characteristics of the mafenide acetate salve, except in liquid form.

Many new antimicrobial dressings containing silver ions have reached the marketplace and provide the advantages listed earlier. Most wound care companies offer a dressing with these characteristics; therefore, the choice among them is principally based on the dressing characteristics, such as a cloth or silicone, elastic or nonelastic, and so on, rather than the antimicrobial properties. The advantage is that these can be applied and left in place for several days, providing for prolonged occlusive treatment for 3 to 7 days typically, and antimicrobial activity. Monitoring of the patient and wound is still indicated because these dressings typically do not allow direct observation of the wound.

The use of perioperative systemic antimicrobials also has a role in decreasing burn wound sepsis until the burn wound is closed. Common organisms that must be considered when choosing a perioperative regimen include *S. aureus, Pseudomonas* species, and *Klebsiella*, which are prevalent in burn wounds.

Synthetic and Biologic Dressings

Synthetic and biologic dressings are an alternative to antimicrobial dressings. These types of dressings provide for stable coverage without painful dressing changes, provide a barrier to evaporative losses, and decrease pain in the wounds. They do not inhibit epithelialization, which is a feature of all topical antimicrobials. These coverings include allograft (cadaver skin), xenograft (e.g., pig skin, fish skin), Biobrane, Suprathel, and dermal equivalent–like products. These should generally be applied within 72 hours of the injury before high bacterial colonization of the wound occurs. Most often, synthetic and biologic dressings are used to cover second-degree wounds while the underlying epithelium heals, or it is used to cover full-thickness wounds for which autograft is not yet available. Each type of dressing has its advantages and disadvantages.

Biologic dressings include xenografts and allografts from cadaver donors. These human skin equivalents are applied to the wounds in the manner of skin grafts, where they engraft and perform the immunologic and barrier functions of normal skin. Thus, these biologic dressings are the optimal wound coverage in the absence of normal skin. Some of these are live tissue, such as fresh or frozen human allograft, whereas other formulations are treated with glycerol to lyse any live cells, leaving the extracellular matrix and proteins intact. Eventually, these biologic dressings will be rejected by usual immune mechanisms, causing the grafts to slough. They can then be replaced, or the open wound can be covered with autograft skin from the patient. Generally, severely burned patients are immunosuppressed, and allograft biologic dressings that have adhered will not reject for several weeks. Biologic dressings can be used to cover any wound as a temporary dressing. They are particularly well suited to massive partial-thickness injuries

(>50% TBSA) to close the wound and allow for healing to take place underneath the dressing. Disadvantages include the possible transmission of viral diseases with allograft and the possibility that a residual mesh pattern will be left from engrafted cadaver dermis if meshed allograft is used.

Biobran and similar products, such as Permeaderm, consist of collagen-coated silicone manufactured into a sheet. Suprathel is another similar formulation, but it is in sheets rather than mesh. These are placed on the wound and become adherent in 24 to 48 hours with dried wound transudate. This sheet then provides a barrier to moisture loss, and it provides a relatively painless wound bed without dressing changes. When the epithelium is complete under the sheet, it is easily peeled off the wound, except for Suprathel, which dissolves. Caution must be exercised when using this product to ensure that copious exudate does not form under the sheet, which provides an optimum environment for bacterial proliferation and risk of invasive wound infection. Biobrane has no antimicrobial activities, whereas Suprathel has some effects because it has a pH of less than 5.5. These agents should be used primarily in superficial second-degree burns and split-thickness skin graft donor sites.

Dermal equivalents such as Integra and Bio-Temporising Matrix (BTM) combine a collagen matrix (dermal substitute) with a silicone sheet outside layer (epidermal substitute). The collagen matrix engrafts into the wound, and after 2 weeks, the silicone layer is removed and replaced with available autograft. The advantages of this product are that it can be used in full-thickness burns to close the wound. It also provides a dermal equivalent that has the theoretical advantage of inhibiting future scarring of the burn wound, although this has not been clinically confirmed to date. The disadvantages are similar to those of all synthetic products, in that it has no antimicrobial properties; thus, its use can be complicated by invasive wound infections. Additionally, it takes two operations for wound coverage, as the silicone layer simulating the epidermis must be replaced 2 to 3 weeks after application with autograft.

In 2021, a novel bioengineered allogeneic cellularized construct was FDA approved for the treatment of burns. This product, StrataGraft (Stratatech, a Mallinckrodt Company, Madison, WI), consists of an immortal, nonimmunogenic, nontumorigenic, karyotypically stable line of human keratinocytes. Human dermal fibroblasts are also embedded in the collagen gel matrix that serves as a scaffold.[43,44] The skin substitute has a complete, stratified epithelial layer that reconstitutes barrier function, as it contains stratum corneum. The product can be meshed and secured to a healthy, postexcision wound bed with fibrin glue, cyanoacrylate, and/or sutures or staples. Several randomized clinical studies bioengineered allogeneic cellularized construct treated wounds, which did not undergo a donor site and had equivalent outcomes to the sites treated with autograft, which did involve a cutaneous donor site. At 3 months, bioengineered allogeneic cellularized construct DNA was not detectable in biopsies, suggesting the product turns over as it stimulates autologous healing. At the time this chapter was written, full thickness burn studies using the product as an overlay for widely meshed autografts had completed enrollment. Data regarding the study was not yet available. Although FDA approved 2 years ago, this product is approximately $40/sq. cm and has not become standard of care. Although it may play a role in reducing donor site size, more clinical data and economic analyses are indicated to drive more widespread use.

Excision and Grafting

Deep partial-thickness and full-thickness burns do not heal in a timely fashion without autografting. In fact, the practice of leaving these dead tissues only serves as a nidus for inflammation and infection that could lead to the patient's death. It leads to the maxim, "there is no advantage to unexcised eschar," as a corollary to the golden rule of burn surgery and wound surgery in general: "close the wound promptly." Early excision and grafting of these wounds, first used by Janzekovich in the 1970s, are followed by most burn surgeons because reports show benefit over serial debridement and dressing changes in terms of survival, blood loss, incidence of sepsis, and length of hospitalization.[45] The technique of early excision and grafting has made conservative management of full-thickness wounds a practice to be used only in those with very high operative risks. Attempts are made to excise tangentially to optimize cosmetic outcome. Rarely, excision to the level of fascia is necessary to remove all nonviable tissue, or it may become necessary at subsequent operations for infectious complications. These excisions can be performed with tourniquet control or with application of topical epinephrine and thrombin to minimize blood loss.

After a burn wound has been excised, the wound must be covered. This covering is ideally the patient's own skin. Wounds covering 20% to 30% TBSA can usually be closed at one operation with autograft split-thickness skin taken from the patient's available donor sites. In these operations, the skin grafts either are not meshed are meshed with a narrow ratio (2:1 or less) to maximize cosmetic outcome. In major burns, autograft skin may be limited to the extent that the wound cannot be completely closed. The availability of cadaver allograft skin has changed the course of modern burn treatment for these massive wounds. A typical method of treatment is to use widely expanded autografts (4:1 or greater) covered with cadaver allograft to completely close the wounds for which autograft is available. The 4:1 skin heals underneath the cadaver skin in approximately 21 days, and the cadaver skin separates. The portions of the wound that cannot be covered with even widely meshed autograft are covered with allograft skin in preparation for autografting when donor sites are healed. Ideally, areas with less cosmetic importance are covered with the widely meshed skin to close most of the wound before using nonmeshed grafts at later operations for the cosmetically important areas, such as the hands, forearms, and face.

Most surgeons excise the burn wound in the first week, sometimes in serial operations by removing portions of the burn wound at operations on subsequent days. Others remove the whole of the burn wound in one operative procedure; however, this can be limited by the development of hypothermia or continuing massive blood loss and experienced anesthesia support. It is our practice to perform the excision immediately after stabilization of the patient after injury because blood loss diminishes if the operation can be done early. This may be caused by the relative predominance of vasoconstrictive substances, such as thromboxane and catecholamines, and the natural edema planes that develop immediately after the injury. When the wound becomes hyperemic after 4 to 7 days, blood loss can be a considerable problem. The use of hemostatic agents, such as epinephrine, thrombin, and tourniquets, sometimes aids in this approach.

Occasionally, split-thickness skin grafts do not adhere. Loss of skin grafts is the result of one or more of the following reasons in order of frequency: inadequate excision of the wound bed with remaining necrotic tissue, shearing forces disrupting an adhered graft, presence of infection causing graft lysis, or fluid collection under the graft. With a good excision and the use of topical antimicrobial agents, infection is *not* common. Technical attention to the depth by excising to punctate bleeding, meticulous hemostasis, appropriate meshing of grafts, or "rolling" of sheet grafts or bolsters over appropriate areas minimizes fluid collections. Shearing is decreased by immobilization of the grafted area. Infection is controlled by the appropriate use of topical antimicrobials at the time of surgery.

One alternative to split-thickness autografts typically used for skin grafting is cultured keratinocytes from the patient's own skin. Keratinocytes can be cultured in sheets from full-thickness skin biopsies, which are used as autografts. This technology has been used to greatly expand the capacity of a donor site, such that most of the body can be covered with grafts from a single small full-thickness biopsy sample. Cultured epithelial autografts are of use in truly massive burns (>80% TBSA) because of their limited donor sites. The disadvantages of cultured epithelial autografts are the length of time required to grow the autografts (2–3 weeks), 50% to 75% take rate of the grafts after initial application, the low resistance to mechanical trauma over the long term, proposed increase in scarring potential associated with the lack of dermis, and the potential for squamous cell cancer. These grafts are also expensive to produce. When a group of patients with greater than 80% TBSA burns who received cultured epithelial autografts were compared with a group who received conventional treatment, the acute hospitalization length of stay and the number of subsequent reconstructive operations were lower in the conventional group. These results demonstrate that more research and experience are needed to further optimize this technique. Technologies like cultured epithelial autografts hold the promise to radically limit donor sites, and it may be the optimal closure in combination with a dermal equivalent in the future.

In this vein, recent technologic advancements in cell separation and expansion by spraying on the operating table have been tested. The RECELL Autologous Skin Cell Suspension (ASCS; RECELL System; AVITA Medical, Valencia, CA) is a point-of-care technique that facilitates a donor skin-sparing approach for burns or other soft tissue defects. In the operating room, a kit is used to prepare an autologous skin cell suspension that can be expanded to 80:1—a sharp increase in expansion from the traditional expansion of conventional grafts. A small skin graft is generally harvested between 6 and 8 one-thousandths of an inch and incubated in an enzyme well to break extracellular attachments. Next, a scalpel is used to perform mechanical delamination of the epidermis and disaggregation of the thin layer of dermis in the sample. The resulting suspension contains mostly keratinocytes, fibroblasts, and melanocytes. This can be applied to a partial-thickness wound, or a meshed autograft can be over-sprayed in the interstices to treat a full-thickness wound. The device is currently approved by the FDA and multiple other regulatory bodies worldwide.

Key evidence for the safety and efficacy of autologous skin cell suspension in burn treatment is available from two prospective, randomized, phase III clinical trials, which were funded by the BARDA.[46,47] Additional data are available from retrospective analyses of patients enrolled in expanded and continued access protocols, including pediatric patients and those with >50% TBSA full-thickness wounds.

One of the two phase III trials evaluated autologous skin cell suspension and autografting versus autografting alone among patients with mixed-depth thermal burns, including full-thickness injuries. An intrapatient control design was employed in which treatment areas were randomly assigned to control (autograft alone) or autologous skin cell suspension plus autografting. Noninferiority of the autologous skin cell suspension to autografting alone was established for wound healing at week 8 (92.3% vs. 84.6%, respectively; treatment difference, –7.7% [one-sided 97.5% CI upper bound, 6.40%]). Additionally, superiority of autologous skin cell suspension was established for relative reduction of donor site harvesting: on average, 32% less donor skin was taken with the use of autologous skin cell suspension ($p < 0.001$). The other phase III trial, which focused on deep partial-thickness burns and studies of patients treated via expanded and continued access protocols, has shown similar results. Additionally, greater overall patient satisfaction and reduced pain have also been reported with the use of autologous skin cell suspension. This product has been shown to reduce length of stay and costs in a subset of complex burn patients.[48] Many surgeons also use the product to treat autograft donor sites, and the myriad of off-label uses is expanding.

In all burned patients, every effort should be made to optimize the long-term appearance of the wound, because almost all patients will survive to bear the scars of their injury. Burn wound scarring causes both functional and cosmetic deficits associated with wound contracture. Experience has shown that full-thickness skin grafts that include the entire dermal and epidermal layer provide the best scarring outcomes, with diminished contracture and superior skin appearance, compared with split-thickness skin grafts. Split-thickness and full-thickness grafts have a complete epidermal layer; therefore, the superior function and appearance of full-thickness grafts lies in the near-complete dermal layer. The challenge to burn surgeons in terms of minimizing scarring, then, is to provide complete dermis during wound coverage. This might be addressed through using thicker split-thickness skin grafts, but our experience suggests that thicker split-thickness grafts do not always result in better scarring. Thick grafts also result in prolonged donor site healing. Therefore, it is reasonable to conclude that standard-thickness skin grafts are appropriate for acute coverage of burn wounds.

Full-thickness skin grafts to supply the dermal layer are not plentiful and cannot be used more than once. The use of tissue expanders to increase available full-thickness donor skin is conceivable, but impractical for most injuries. For these reasons, these grafts are not commonly used in acute burn wound coverage. Engrafted cadaver dermis that has the epidermis removed by dermabrasion 1 to 2 weeks after placing it on the wound has been used with some success to provide the dermal layer. Presumably, the sparse cellular component of the dermis is removed by immunologic processes, leaving the dermal matrix in place as scaffolding for the ingrowth of normal dermal cells. Some commercially available decellularized preserved dermis products are available to provide a dermal equivalent in wound coverage. As discussed earlier, the products Integra and BTM also have a dermal-equivalent component to form a neo-dermis. All of these have the potential to minimize scarring contractures and to maximize the cosmetic appearance of burn scars. The long-term results with the use of these techniques are not yet known.

Minimally Invasive Skin Grafting

When dermal-sparing excision techniques are used, the chances of spontaneous healing with an acceptable outcome are increased. Some of the novel products described in this chapter stimulate autologous healing with human cells. Autologous skin cell suspension uses the patient's own cells, and BACC is an allograft-based product. Kahn et al. published their experience using these products in combination with bromelain-based chemical escharotomy followed by treatment with autologous skin cell suspension. After an initial proof-of-concept/feasibility study, they achieved approximately a 300% reduction in donor site size in patients with a mix of deep partial-thickness and full-thickness burns.[49]

As early as 2 hours after the bromelain is removed, the areas that are clearly full thickness received meshed split-thickness skin grafts with an autologous skin cell suspension overspray, whereas deep to middepth partial-thickness injuries received cell suspension spray alone. Depending on wound and patient characteristics, this is then dressed with polylactic acid sheets (Suprathel) or high-density porous polyethylene film as a primary dressing with periodic secondary dressing changes every few days. Several burn centers across the United States use this approach successfully. The technique is in its infancy; further study and optimization are forthcoming. Many of the studies that brought these products to market were funded by the DoD/BARDA, with the goal of using them synergistically as "multiple medical countermeasures" not only for mass casualty events but also developing the products to be a routine component in both military and civilian burn care.

The idea of enhanced recovery after burn injury has not been well characterized in the literature. However, many centers already use key components of standard programs, particularly related to temperature monitoring, fluids, and nutrition. The idea of enhanced recovery after burn surgery first presented as a formal protocol in 2018, approximately 20 years after it was first described for any patient, by Henrik Kehlet.[50] In addition to the strategies noted earlier, narcotic reduction through multimodal pharmacologic approaches combined with skin substitutes and glues instead of aggressive use of staples and sutures may reduce the need for sedation and heavy narcotic use.

MINIMIZING COMPLICATIONS

Early aggressive resuscitation regimens have improved survival rates dramatically. With the advent of vigorous fluid resuscitation, irreversible burn shock has been replaced by sepsis and subsequent multiple organ failure as the leading cause of death associated with burns. What is required is an inflammatory focus, which in severe burns is the massive skin injury with associated inflammation that is required to heal.

Etiology and Pathophysiology

The progression to multiple organ failure after severe burn is not well explained, although some of the responsible mechanisms are recognized. As shown in the Glue Grant data, massive changes in the inflammatory genome are already present in those who are severely burned; development of infectious sources is not uncommon, mostly associated with the burn wound but also from other sources such as the lungs. As organisms proliferate out of control, mediators are liberated from both microbes and endogenous sources such as mitochondria. Their release is associated with a cascade of inflammatory mediators that can result, if unchecked, in further damage and progression toward organ failure.

Inflammation from the presence of necrotic tissue and open wounds can incite a similar inflammatory mediator response. It is known that a cascade of systemic events is set in motion either by invasive organisms or from open wounds that initiate massive inflammation, which may progress to multiple organ failure. Evidence from animal studies and clinical trials suggests that these events converge to a common pathway. Those circulating mediators can, if secreted in excessive amounts, damage organs distal from their site of origin. Among these mediators are endotoxin, the arachidonic acid metabolites, mitochondrial fragments, cytokines, neutrophils and their adherence molecules, nitric oxide, complement components, and oxygen free radicals.

Prevention

Because different cascade systems are involved in the pathogenesis of burn-induced multiple organ failure, it is so far impossible to pinpoint a single mediator that initiates the event. Thus, because the mechanisms of progression are not well known, prevention is currently the best solution. The current recommendations are to prevent the development of organ dysfunction and to provide optimal support to avoid conditions that promote the onset. The great reduction of mortality rate from large burns was seen with early excision and an aggressive surgical approach to deep wounds; thus, the best solution is likely early wound closure.

Removal of devitalized tissue prevents wound infections and decreases inflammation associated with the wound. In addition, it eliminates small-colonized foci, which are a frequent source of transient bacteremia. Transient bacteremia during surgical manipulations may prime immune cells to react in an exaggerated fashion to subsequent insults, leading to whole body inflammation and remote organ damage. We recommend complete early excision of clearly full-thickness wounds within 48 hours of the injury with rapid closure of the wound by autologous skin grafting or skin substitute.

Oxidative damage from reperfusion after low-flow states makes early aggressive fluid resuscitation imperative. This is particularly important during the initial phases of treatment and operative excision with its attendant blood losses. Furthermore, the volume of fluid may not be as important as the timeliness with which it is given. In a study of children with greater than 80% TBSA burns, it was found that one of the most important contributors to survival was the time to starting intravenous resuscitation, regardless of the initial volume given.

Topical and systemic antimicrobial therapy has significantly diminished the incidence of invasive burn wound sepsis. Perioperative systemic antibiotics likely benefit patients with injuries greater than 30% TBSA burns. Vigilant and scheduled replacement of intravascular devices minimizes the incidence of catheter-related sepsis. Where possible, peripheral veins should be used for cannulation, even through burned tissue. New technologies such as central access through peripheral veins also likely decreases the incidence of line sepsis.

Pneumonia, which contributes significantly to death in burned patients, should be vigilantly anticipated and aggressively treated. Every effort should be made to wean patients as early as possible from the ventilator to reduce the risk of ventilator-associated nosocomial pneumonia. Furthermore, early ambulation is an effective means of preventing respiratory complications. With sufficient analgesics, even patients on continuous ventilatory support can be out of bed and in a chair.

The most common sources of sepsis are the wounds and/or the tracheobronchial trees; efforts to identify causative agents should be concentrated there. Another potential source, however, is the gastrointestinal tract, which is a natural reservoir for bacteria. Starvation and hypovolemia shunt blood from the splanchnic bed and promote mucosal atrophy and failure of the gut barrier. Early enteral feeding reduces septic morbidity and prevents failure of the gut barrier. At our institution, patients are fed immediately through a nasogastric tube. Early enteral feedings are tolerated in burn patients and preserve mucosal integrity and likely reduce the magnitude of the hypermetabolic response to injury. Support of the gut goes along with carefully monitored hemodynamics. One other infection to consider, usually late in the course, is endocarditis with microbes associated with the cardiac valves usually late in the course of treatment. This can be detected with echocardiography and should be considered in the face of infection for which no other source is identified.

Organ Failure

Even with the best efforts at prevention, the presence of the systemic inflammatory syndrome, which is ubiquitous in burn patients, may progress to organ failure. It was found that approximately 28% of patients with greater than 20% TBSA burns develop severe multiple organ dysfunction, of which 14% also develop severe sepsis and septic shock. Around 40% of deaths after severe burn are related to organ failure, which universally involves the renal system with, on average, at least three other systems. The general development begins in the renal or pulmonary systems and can progress through the liver, gut, hematologic system, and central nervous system. The development of multiple organ failure does not accurately predict mortality but does increase risk. Therefore, efforts to support the organs until they heal are justified.

Renal Failure

With the advent of early aggressive resuscitation, the incidence of renal failure coincident with the initial phases of recovery has diminished significantly in severely burned patients. However, a second period of risk for the development of renal failure 2 to 14 days after resuscitation is still present. Renal failure is hallmarked by decreasing urine output, hypervolemia, electrolyte abnormalities including metabolic acidosis and hyperkalemia, the development of azotemia, and increased serum creatinine. Treatment is aimed at averting complications associated with these conditions.

Urine output of more than 1 mL/kg/h in children and 30 cc/h in adults is an adequate measure of renal perfusion in the absence of underlying renal disease. Decreasing the volume of fluid given alleviates volume overload in burned patients. These patients have increased insensible losses from the wounds, which can be roughly calculated at 1500 mL/m^2 TBSA + 3750 mL/m^2 TBSA burned. Decreasing the infused volume of intravenous fluids and enteral feedings to less than the expected insensate losses alleviates hypervolemia problems. Almost invariably, severely burned patients receive exogenous potassium because of the heightened aldosterone response that results in potassium wasting; therefore, hyperkalemia is rare even with some renal insufficiency.

If the problems listed earlier overwhelm the conservative measures, some form of dialysis may be indicated. The indications for dialysis are hypervolemia unresponsive to diuretics or electrolyte abnormalities not amenable to other treatments. Kidney Disease: Improving Global Outcomes (KDIGO) criteria may be used to determine utility of dialysis, and level 3 or severe acute renal failure indicates use. Hemodialysis and hemofiltration are the most common modalities, either intermittent or continuous. With the advent of relatively simple continuous renal replacement technologies, these treatments can often be managed by critical care specialists with consultation from experienced nephrologists in difficult cases. After beginning dialysis, renal function is almost certain to return, associated with the abundant regeneration properties of the kidney in the absence of preexisting disease. Therefore, patients undergoing such treatment rarely undergo lifelong dialysis.

Pulmonary Failure

Many burn patients undergo mechanical ventilation to protect the airway in the initial phases of their injury. We recommend these patients be extubated as soon as possible after the risk is diminished. A trial of extubation is often warranted in the first few days after injury, and reintubation in this setting is not a failure. Performing this technique safely, however, requires the involvement of experts in obtaining an airway. The goal is extubation as soon as possible to allow the patients to clear their own airways, because they can perform their own pulmonary toilet better than through an endotracheal tube or tracheostomy. Often, the first sign of impending pulmonary failure is a decline in oxygenation. This is best monitored with continuous oximetry, and a decrease in saturation to less than 92% is indicative of failure. Increasing concentrations of inspired oxygen are necessary, and when ventilation begins to fail, denoted by increasing respiratory rate and hypercarbia, intubation is indicated.

Some have stated that early tracheostomy (within the first week) might be indicated in those with significant burn who are likely to require long-term ventilation. A randomized study comparing those severely burned patients who underwent early tracheostomy with those who did not found some early improvements in oxygenation; however, no significant differences were found in outcome measures such as ventilator days, length of stay, incidence of pneumonia, or survival. In fact, 26% of those not undergoing tracheostomy were successfully extubated within 2 weeks of admission, implying that they would not have benefited from tracheostomy at all. Tracheostomy also has its risks, which are often overlooked, including acute loss of airway and, most importantly, lifelong risk of aspiration associated with anatomic changes in the neck. It seems that although tracheostomy may benefit some severely burned patients on ventilatory support, the advantages of early tracheostomy do not always outweigh the disadvantages.

Hepatic Failure

The development of hepatic failure in burned patients is a challenging problem without many solutions. The liver synthesizes circulating proteins, detoxifies the plasma, produces bile, and provides immunologic support. When the liver begins to fail, protein concentrations of the coagulation cascade decrease to critical levels and the patient becomes coagulopathic. Toxins are not cleared from the bloodstream, and concentrations of bilirubin increase. Complete hepatic failure is not compatible with life, but a gradation of liver failure with some decline of the function is common. Efforts to prevent hepatic failure are the only effective methods of treatment.

With the development of coagulopathies, treatment should be directed at replacement of factors II, VII, IX, and X until the liver recovers. Albumin replacement may also be indicated. Attention to obstructive causes of hyperbilirubinemia, such as acalculous cholecystitis, should be considered as well. Initial treatment of this condition should be gallbladder drainage, which can be done percutaneously in those at high risk.

Hematologic Failure

Burn patients may become coagulopathic through two mechanisms: (1) depletion and impaired synthesis of coagulation factors or (2) thrombocytopenia. Issues associated with factor depletion are through disseminated intravascular coagulation often associated with sepsis. This process is also common with coincident head injury. With breakdown of the blood-brain barrier, brain lipids are exposed to the plasma, which activates the coagulation cascade. Varying penetrance of this problem results in differing degrees of coagulopathy. Treatment of disseminated intravascular coagulation should include infusion of fresh frozen plasma and cryoprecipitate to maintain plasma levels of coagulation factors best monitored with dynamic coagulation testing with thromboelastography. Impaired synthesis of factors from liver failure is treated, as alluded to earlier.

Thrombocytopenia is common in severe burns from depletion during burn wound excision and is one of the best signs of the development of sepsis. Platelet counts of less than 50,000 are common and do not require treatment. Only when the bleeding is diffuse and is noted from the intravenous sites should consideration for exogenous platelets be given.

Paradoxically, it was found that severely burned patients are also at risk for thrombotic and embolic complications likely related to immobilization. Complications of deep venous thrombosis was associated with increasing age, weight, and TBSA burned.

NUTRITION

The response to injury known as *hypermetabolism* is dramatically exhibited after severe burn. Increases in oxygen consumption, metabolic rate, urinary nitrogen excretion, and lipolysis are directly proportional to the size of the burn. This response can be as high as 200% of the normal metabolic rate and continues unabated for 9 to 12 months after injury. Because the metabolic rate is so high, energy utilization is immense. Endogenously, these are met by mobilization of available carbohydrate, fat, and protein stores. Because the demands are prolonged, these energy stores are depleted, leading to loss of active muscle tissue and malnutrition. Immobilization for treatment further worsens the condition, leading to malnutrition. This is associated with functional impairment of many organs, delayed and abnormal wound healing, and decreased immunocompetence. Malnutrition in burns can be subverted to some extent by delivery of adequate exogenous nutritional support, but the goals of this treatment are principally to prevent nutritional complications.

Several formulas are used to calculate caloric requirements in burn patients. One multiplies the basal energy expenditure determined by the Harris-Benedict formula by 2 in burns greater than 40% TBSA, assuming a 100% increase in total energy expenditure. When total energy expenditure was measured by the doubly labeled water method, actual expenditures were found to be 1.3 times the predicted basal energy expenditure for pediatric patients with burns greater than 40% TBSA.[51] When measured during convalescence after initial hospitalization, it remained elevated at 1.1 times predicted energy expenditure.[52] These studies indicate that the calculation of 2 times the predicted basal energy expenditure might be too high.

Another commonly used calculation is the Curreri formula, which calls for 25 kcal/kg/day plus 40 kcal per percent TBSA burned per day. This formula provides for maintenance needs plus the additional caloric needs related to the burn wounds. This formula was devised as a regression from nitrogen balance data in severely burned adults. In children, formulas based on body surface area are more appropriate because of the greater body surface area per kilogram of weight. We recommend the following formulas depending on the child's age (Table 43.6). These formulas were determined to maintain body weight in severely burned children. The formulas change with age based on the body surface area alterations that occur with growth.

The composition of the nutritional supplement is also important. The optimal dietary composition contains 1 to 2 g/kg/day of protein, which provides a calorie-to-nitrogen ratio at around 100:1 with the earlier suggested caloric intakes. This amount of protein provides for the synthetic needs of the patient, thus sparing to some extent the proteolysis occurring in the active muscle tissue. Nonprotein calories can be given as either carbohydrate or fat. Carbohydrates have the advantage of stimulating endogenous insulin production, which has beneficial effects on muscle and the burn wounds as an anabolic hormone.[53] In addition, it was shown that almost all of the fat transported in very-low-density lipoprotein after severe burn is derived from peripheral lipolysis and not from de novo synthesis of fatty acids in the liver from dietary carbohydrates.[53] Reliance on fat to deliver noncarbohydrate calories thus has little support.

TABLE 43.6 **Formulas to Predict Calorie Needs in Severely Burned Children**

AGE GROUP	MAINTENANCE NEEDS	BURN WOUND NEEDS
Infants (0–12 months)	2100 kcal/% TBSA burned/24 hours	1000 kcal/% TBSA burned/24 hours
Children (1–12 years)	1800 kcal/% TBSA burned/24 hours	1300 kcal/% TBSA burned/24 hours
Adolescents (12–18 years)	1500 kcal/% TBSA burned/24 hours	1500 kcal/% TBSA burned/24 hours

TBSA, Total body surface area.

The diet may be delivered in two forms: either enterally through enteric tubes or parenterally through intravenous catheters. Parenteral nutrition may be given in isotonic solutions through peripheral catheters or with hypertonic solutions in central catheters; however, the caloric demands of burn patients prohibit the use of peripheral parenteral nutrition. Total parenteral nutrition delivered centrally in burned patients has been associated with increased complications and mortality rate compared with enteral feedings. Total parenteral nutrition is reserved only for those patients who cannot tolerate enteral feedings. Enteral feeding has been associated with some complications, however, which can be disastrous. These include mechanical complications, enteral feeding intolerance, and diarrhea.

Nutritional adjunctive treatment with anabolic agents has received attention as a means to decrease lean mass losses after severe injury. Agents used include growth hormone, insulin-like growth factor, insulin, oxandrolone, testosterone, and propranolol. Studies supporting the use of each are now over 12 years old and mature. Of these oxandrolone and propranolol were the most commonly used. However, oxandrolone has been removed from the marketplace by the FDA. In combination, each of these agents has different actions to stimulate protein synthesis through an increase in protein synthetic efficiency. Put simply, the free amino acids available in the cytoplasm from protein breakdown with severe injury or illness are preferentially shunted toward protein synthesis rather than exported out of the cell.

LESS COMMON BURN ETIOLOGIES

Electrical Burns

Of all admitted burned patients, 3% to 5% are injured from electrical contact. Electrical injury is unlike other burns in that the visible areas of tissue necrosis represent only a small portion of the injured tissue. Electrical current enters a part of the body, such as the fingers or hand, and proceeds through tissues with the lowest resistance to current, generally nerves, muscles, and blood vessels. The skin has a relatively high resistance to electrical current and is therefore mostly spared. The current then leaves the body at a "grounded" area on some other part of the body. Heat generated by the transfer of electrical current and passage of the current itself then injures the tissues. During this exchange, the muscle is the major tissue through which the current flows and thus sustains the most damage. Most muscle is in close proximity to bones; therefore, that is where the most injury is evident. The bone itself does not sustain any increase in temperature or injury. Blood vessels transmitting much of the electricity initially remain patent, but they may proceed to progressive thrombosis as the cells either die or repair themselves, thus resulting in further tissue loss from ischemia that might be evident days later.

Injuries are divided into high- and low-voltage injuries. Low-voltage injury is similar to thermal burns without transmission to the deeper tissues; zones of injury from the surface extend into the tissue. Most household currents (110–220 volts) produce this type of injury, which usually causes only local damage. The worst of these injuries are those involving the edge of the mouth (oral commissure) sustained when children gnaw on household electrical cords with alternating current. Most households are on direct current; therefore, these types of injuries are now rare.

The syndrome of high-voltage injury consists of varying degrees of cutaneous burn at the entry and exit sites, combined with hidden destruction of deep tissue. Often, these patients also have cutaneous burns associated with ignition of clothing from the discharge of electrical current. In these cases, the burns on the skin are mostly thermal and not electrical and should be treated as such. Initial evaluation consists of cardiopulmonary resuscitation if ventricular fibrillation is induced. Thereafter, if the initial electrocardiogram findings are abnormal or with a history of cardiac arrest associated with the injury, continued cardiac monitoring is indicated along with pharmacologic treatment for any dysrhythmias. The most serious derangements occur in the first 24 hours after injury. If patients with electrical injuries have no cardiac dysrhythmias on initial electrocardiogram or recent history of cardiac arrest, no further monitoring is necessary.

Patients with electrical injuries are at risk for other injuries, such as being thrown from the electrical jolt or falling from heights after disengaging from the electrical current. In addition, the violent tetanic muscular contractions that result from alternating current sources may cause a variety of fractures and dislocations. These patients should be assessed as any other patient with blunt traumatic injuries.

The key to managing patients with an electrical injury lies in the treatment of the wound. The most significant injury is within the deep tissue, and subsequent edema formation can cause vascular compromise to any area distal to the injury. Assessment should include circulation to distal vascular beds, because immediate escharotomy and fasciotomy may be indicated. If the muscle compartment is extensively injured and necrotic, such that the prospects for eventual function are dismal, early amputation may be indicated. We advocate early exploration of affected muscle beds and excision of devitalized tissues with attention given to the deeper periosteous planes, because this is the area with the most muscle. Fasciotomies should be complete and may include nerve decompressions, such as carpal tunnel and Guyon canal releases. Tissue that has questionable viability should be left in place, with planned reexploration. Many such reexplorations may occur until the wound is completely controlled. Electrical damage to vessels may be delayed, and the extent of necrosis may extend after the initial procedures.

After the devitalized tissues are removed, closure of the wound becomes paramount. Although skin grafts suffice as closure for most wounds, flaps may offer a better alternative, particularly with exposed bones and tendons. Even exposed and superficially infected bones and tendons can be salvaged with coverage by vascularized tissue. Early involvement by reconstructive surgeons versed in the various methods of wound closure is optimal.

Muscle damage results in release of hemochromogens (myoglobin), which are filtered in the glomeruli and may result in obstructive nephropathy. Therefore, vigorous hydration and infusion of intravenous sodium bicarbonate (5% continuous infusion) and mannitol (25 g every 6 hours for adults) were historically used to solubilize the hemochromogens and maintain urine output if significant amounts are found in the serum, though this has been questioned. These patients also benefit from additional intravenous volumes over predicted amounts for the wound area because most of the wound is deep and cannot be assessed by physical examination.

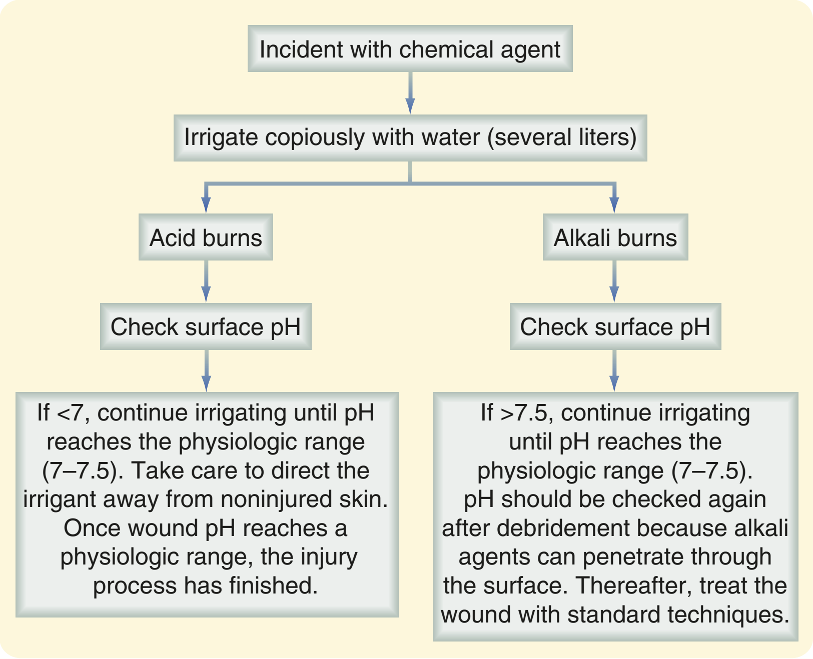
Neurologic deficits may occur that may seem somewhat random. Serial neurologic evaluations should be performed as part of routine examination in order to detect any early or late neuropathology. Central nervous system effects such as cortical encephalopathy, hemiplegia, aphasia, and brainstem dysfunction injury have been reported up to 9 months after injury; others report delayed peripheral nerve lesions characterized by demyelination with vacuolization and reactive gliosis. Another devastating long-term effect is the development of cataracts, which can be delayed for several years. These complications may occur in up to 30% of patients with significant high-voltage injury, and patients should be made aware of this risk even with the best treatment.

CHEMICAL BURNS

Most chemical burns are incidental from mishandling of household cleaners, although some of the most dramatic presentations involve industrial exposures. Thermal burns are, in general, short-term exposures to heat, but chemical injuries may be of longer duration, even for hours in the absence of appropriate treatment. The degree of tissue damage as well as the level of toxicity are determined by the chemical nature of the agent, concentration of the agent, and the duration of skin contact. Chemicals cause their injury by protein destruction, with denaturation, oxidation, formation of protein esters, or desiccation of the tissue. In the United States, the composition of most household and industrial chemicals can be obtained from the Poison Control Center in the area, which can give suggestions for treatment.

Speed is essential in the management of chemical burns. For all chemicals, lavage with copious quantities of clean water should be done immediately after removing all clothing. Dry powders should be brushed from the affected areas before irrigation. Early irrigation dilutes the chemical, which is already in contact with the skin, and timeliness increases effectiveness of irrigation; several liters of irrigant may be used. For example, 10 mL of 98% sulfuric acid dissolved in 12 L of water decreases the pH to 5.0, a range that can still cause injury. If the chemical composition is known (acid or base), monitoring of the spent lavage solution pH gives some indication of lavage effectiveness and completion. A reasonable rule of thumb is to lavage with 15 to 20 L of tap water or more for significant chemical injuries. The lavage site should be kept drained in order to remove the earlier, more concentrated effluent. Care should be taken to drain away from uninjured areas to avoid further exposure (Fig. 43.10).

All patients must be monitored according to the severity of their injuries. They may have metabolic disturbances, usually from pH abnormalities, because of exposure to strong acids or caustics. If respiratory difficulty is apparent, oxygen therapy and mechanical ventilation must be instituted. Resuscitation should be guided by the body surface area involved (burn formulas); however, the total fluids given may be dramatically different from the calculated volumes. Some of these injuries may be more



Incident with chemical agent
Irrigate copiously with water (several liters)
Acid burns
Alkali burns
Check surface pH
Check surface pH

If <7, continue irrigating until pH reaches the physiologic range (7–7.5). Take care to direct the irrigant away from noninjured skin. Once wound pH reaches a physiologic range, the injury process has finished.

If >7.5, continue irrigating until pH reaches the physiologic range (7–7.5). pH should be checked again after debridement because alkali agents can penetrate through the surface. Thereafter, treat the wound with standard techniques.

FIGURE 43.10 Treatment of acid and alkali burns.

superficial than they appear, particularly in the case of acids because of coagulative necrosis, and therefore have less resuscitation volume. Injuries from bases, however, may penetrate beyond that which is apparent on examination (liquefactive necrosis); therefore, more volume might be indicated. For this reason, patients with chemical injuries should be observed closely for signs of adequate perfusion. All patients with significant chemical injuries should be monitored with indwelling bladder catheters to accurately measure outputs.

Operative excision, if indicated by clinical assessment of wound depth, should take place as soon as the patient is stable and resuscitated. After adequate lavage and excision, burn wounds are covered with antimicrobial agents or skin substitutes. Once the wounds have stabilized with the indicated treatment, they are taken care of as with any loss of soft tissue. Skin grafting or flap coverage is performed as indicated.

For alkali burns in particular, these are often from chemicals such as lime, potassium hydroxide, bleach, and sodium hydroxide and are among the most common agents involved in chemical injury. Incidental injury frequently occurs in infants and toddlers exploring cleaning cabinets. Three factors are involved in the mechanism of alkali burns: (1) saponification of fat causes the loss of insulation of heat formed in the chemical reaction with tissue, (2) massive extraction of water from cells causes damage because of the hygroscopic nature of alkali, and (3) alkalis dissolve and unite with the proteins of the tissues to form alkaline proteinates, which are soluble and contain hydroxide ions. These ions induce further chemical reactions, penetrating deeper into the tissue. Treatment involves immediate removal of the causative agent with lavage of large volumes of fluid, usually water. Attempts to neutralize alkali agents with weak acids are not recommended because the heat released with neutralization reactions compounds the injury through the thermoplastic reaction. Particularly strong bases should be treated with lavage and consideration for the addition of wound debridement in the operating room. Tangential removal of affected areas is performed until the tissues removed are at a normal pH.

Cement (calcium oxide) burns are alkali in nature, occur commonly, and are usually work-related injuries. The critical substance responsible for the skin damage is the hydroxyl ion. Often, the agent has been in contact with the skin for prolonged periods, such as underneath the boots of a cement worker who seeks treatment hours after the exposure or after the cement penetrates clothing and, when combined with perspiration, induces an exothermic reaction. Treatment consists of removing all clothing and irrigating the affected area with water and soap until all the cement is removed and the effluent has a pH of less than 8. Injuries tend to be deep because of exposure times, and surgical excision and grafting of the resultant eschar may be indicated.

Acid injuries are treated initially like any other chemical injury, with removal of all chemicals by disrobing the affected area and copious irrigation. Acids such as sulfuric or hydrochloric acid induce protein breakdown by hydrolysis and coagulative necrosis, which results in a hard eschar that does not penetrate as deeply as the alkalis. These agents also induce thermal injury by heat generation with contact of the skin, further causing soft tissue damage.

Formic acid injuries are relatively rare, usually involving an organic acid for industrial descaling and as a hay preservative. Electrolyte abnormalities are of great concern for patients with extensive formic acid injuries, with metabolic acidosis, renal failure, intravascular hemolysis, and pulmonary complications being common. Acidemia detected by a metabolic acidosis on arterial blood gas analysis should be corrected with intravenous sodium bicarbonate. Hemodialysis may be indicated when extensive absorption of formic acid has occurred. A formic acid wound typically has a greenish appearance and is deeper than what it initially appears to be; it is best treated by surgical excision.

Hydrofluoric acid is a toxic substance used widely in both industrial and domestic settings and is the strongest known inorganic acid. Management of these burns differs from other acid burns in general. Hydrofluoric acid produces dehydration and corrosion of tissue with free hydrogen ions. In addition, the fluoride ion complexes with bivalent cations such as calcium and magnesium to form insoluble salts. Systemic absorption of the fluoride ion then can induce intravascular calcium chelation and hypocalcemia, leading to life-threatening arrhythmias. Beyond initial copious irrigation with clean water, the burned area should be treated immediately with copious 2.5% calcium gluconate gel. These wounds in general are quite painful because of the calcium chelation and associated potassium release; this finding can be used to determine the effectiveness of treatment. The gel should be changed at 15-minute intervals until the pain subsides, an indication of removal of the active fluoride ion. If pain relief is incomplete after several applications or symptoms recur, intradermal injections of 10% calcium gluconate (0.5 mL/cm^2 affected), intraarterial calcium gluconate into the affected extremity, or both may be used to alleviate symptoms. If the burn is not treated in such a fashion, decalcification of the bone underlying the injury and extension of the soft tissue injury may occur.

All patients with hydrofluoric acid burns should be admitted for cardiac monitoring, with particular attention paid to prolongation of the QT interval. A total of 20 mL of 10% calcium gluconate solution should be added to the first liter of resuscitation fluid, and serum electrolytes must be closely monitored. Any electrocardiographic changes should institute a rapid response by the treatment team with intravenous calcium chloride to maintain heart function. Several grams of calcium may be needed until the chemical response has run its course. Serum magnesium and potassium also should be closely monitored and replaced. Speed is the key to effective treatment.

The organic solvent properties of hydrocarbons promote cell membrane dissolution and skin necrosis. Symptoms include erythema and blistering, and the burns are typically superficial and heal spontaneously. If absorbed systemically, toxicity can produce respiratory depression and eventual hepatic injury thought to be associated with benzenes. Ignition of the hydrocarbons on the skin induces a deep full-thickness injury.

Friction Burns

Friction burn usually presents in two distinct forms: contact with a high-speed motorized belt such as a treadmill or “road rash.” Friction burn from the ground (road rash) is a unique injury that has both thermal and mechanical components, adding significant complexity to the wound. First, the heat generated from the friction between the skin and the abrasive surface creates a thermal injury. The severity of injury is determined by the texture of the surface, velocity of the skin when it impacts, temperature of the surface (climate, ambient temperature, time of day), protection by clothing, force generated between the ground and body, and anatomic location. Injury will generally be worse in areas of thin tissue, particularly over bony prominences. Mechanically, these wounds often contain abrasions, lacerations, avulsions, and degloving injuries. Furthermore, a deeper vascular shear or direct impact and tissue death can result in hematomas and skin/fat/muscle necrosis. These patients often have other injuries such as fractures, solid organ injury, and head injury, further complicating their course. Nonviable wound edges may not be amenable to closure and often have irregular, stellate patterns. Finally, these often have significant environmental contamination and are at higher risk of infection.

Most burn centers treat friction burn similarly to other burns with dressing changes, skin substitutes, and more invasive procedures when necessary. Many of these patients benefit from an aggressive lavage with heavy sedation or general anesthesia to remove contaminants. These wounds also have the risk of tattooing the dermis with contaminating materials.

SUMMARY

The treatment of burns is complex. Minor injuries can be treated in the community by knowledgeable physicians. Moderate and severe injuries, however, benefit from treatment in dedicated facilities with resources to maximize the outcomes from these often-devastating events. Care of patients has markedly improved such that most patients even with massive injuries survive. Challenges for the future will be in the areas of scar minimization and control and acceleration of the healing time to result in functional and visually appealing outcomes.

CHAPTER 44

The Outdoors—Venomous Bites and Stings and Environmental Exposure

John Patrick Walker and Gregory J. Jurkovich

OUTLINE

Snakebites
- Snake Epidemiology
- Snake Venom Composition and Consequences
- Snakebite Management
- Elapid Snake Epidemiology, Envenomation, and Treatment

Venomous Lizards

Insect Bites and Stings
- Spiders
- Hymenoptera
- Fire Ants
- Scorpions
- Centipedes and Millipedes
- Asp Caterpillars

Environmental Exposure
- Hypothermia
- Hypothermia in Trauma Patients
- Treatment of Primary or Accidental Hypothermia
- Cold Injury and Frostbite
- Treatment of Cold Injury

Summary

SNAKEBITES

The legends and lore of snakes are spread across history, with serpents mentioned in 42 Bible verses, implicated in the death of Cleopatra, and featured in the medical field—the snake is essential to the rod of Aesculapius and the Caduceus. Few emergencies have been surrounded with as many types of attempted but ineffective treatments (e.g., electrical shock and TASER, tourniquets with ice emersion, crosscut of the bite with suction of the wound) and little scientific fact as a snakebite. We will address the management of snakebites and related envenomation with scientific evidence.

Snake Epidemiology

The World Health Organization (WHO) estimates that 5.4 million people worldwide are bitten by snakes each year, with 1.8 to 2.7 million cases of envenomation. This organization also estimates between 81,000 and 138,000 deaths a year and three times as many amputations and permanent disabilities. High-quality snake antivenoms are considered essential medicines by the WHO. In the United States, the Centers for Disease Control and Prevention (CDC) estimates there are 7000 to 8000 bites per year, resulting in five to six deaths. Most of the deaths are secondary to rattlesnake envenomation, with only two fatalities from copperhead snakebite in the past 5 years. More than 3700 species of snakes exist in the world, of which approximately 200 are deadly. They range in size from 10 cm to greater than 9 m. Nonvenomous snakes predominate on all continents except for Australia.

There are four families of poisonous snakes worldwide: *Colubridae*, *Elapidae* (which now includes the *Hydrophiinae*—the sea snakes), *Viperidae*, and *Atractaspididae*. The boomslang and the bird snake represent the *Colubridae*—found mostly in Africa. The Elapids are found throughout the world and include snakes such as mambas, kraits, adders, and cobras. The only Elapids in North America are the coral snakes. The Viperids have long hinged fangs. They include the pit vipers that, like the nonvenomous *Boidae* family (boas and pythons), have infrared sensors in a nasal pit that is located between the nose and the eye (Fig. 44.1). These are excellent sensory organs that can differentiate a temperature differential of 0.003°C.

All venomous snakes in North America, except for the coral snakes, are in this *Viperidae* family. The phylogeny of poisonous snakes in North America is therefore that of the phylum Chordata, class Reptilia, order Squamata, suborder Serpentes, and of the *Crotalidae* (subfamily *Crotalinae*) or *Elapidae* family. Venomous snakes are distributed throughout the United States, with at least one species in every state except for Hawaii, Alaska, and Maine. Water moccasins are found primarily in the southeastern United States. Copperheads are found from Massachusetts westerly to Illinois and to the south from Florida to Texas. Rattlesnakes are found from coast to coast. The genus *Crotalus*—the true rattlesnakes—is found only in the Americas.

Snakes are easily identifiable reptiles, marked anatomically by the large number (greater than 120) of precloacal vertebral bodies. They also have a reduced (almost absent) left lung, a single ventricle (no ventricular septum), and no muscles in the ciliary body of the eye. Despite the absence of a ventricular septum, oxygenated and deoxygenated blood channels separately though the heart. All snakes are strictly carnivores. The size of the snake dictates the size of the prey.

In the management of snakebite, one of the most important steps is identification of the species of the offending serpent. In the United States, this is less important than in other countries because almost all venomous bites are from the genera *Crotalus* and *Sistrurus* (e.g., rattlesnakes and pigmy rattlers) and the genera Agkistrodon (e.g., copperheads and water moccasins). All of these are treated in a similar fashion, with the same antivenom. The only exception is envenomation by the coral snakes (an Elapid).

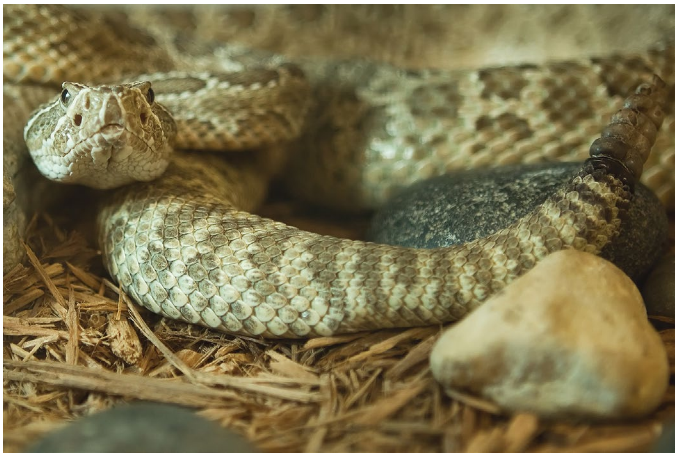

FIGURE 44.1 Depiction of nasal pits that are located between the nose and the eye, which are excellent sensory organs and contain a membrane that can detect infrared radiation from warm bodies up to 1 m away.

Note that manufacture of antivenom for coral snakes was discontinued in the United States (however, this antivenom is available in other countries), although a few vials may still exist, likely of decreased potency.

In North America, there are two genera of rattlesnakes: *Crotalus* (Table 44.1), or the true rattlesnakes, and *Sistrurus* (Table 44.2), or the pigmy rattlers. There are 14 species of *Crotalus* in North America. The remainder of the pit vipers fall into the members of the *Agkistrodon* genus—moccasins and copperheads (Table 44.3). The largest species of rattlesnake in North America is the eastern diamondback *(Crotalus adamanteus),* which is slightly larger than its cousin, the western diamondback *(Crotalus atrox).* These pit vipers (i.e., genus *Crotalus*, *Sistrurus*, and *Agkistrodon*) are morphologically distinguished by elliptical pupils, a triangular head (Fig. 44.2), and retractable fangs. The fangs are tubular, injecting venom similar to a hypodermic needle. This is in contradistinction to the Elapids, in which the fangs are fixed and grooved, wicking the venom into the victim. Venomous snakes have a single row of caudal plates distal to the anal plate, whereas nonvenomous snakes have a double row of caudal plates.

There are 32 species of rattlesnakes in the Americas, ranging from southern Alberta to central Argentina. Rattlesnakes are only found in the Americas. All true rattlesnakes have a rattle (except for an endangered species in Mexico—the Santa Catalina rattlesnake, which has only a vestigial rattle). The rattle is a series of interlocking segments. A new segment is added with each shedding of the skin. Venom is produced in Duvernoy glands on the dorsal sides of the head (corresponding to parotid glands), enhancing the triangular appearance. During envenomation, the venom is forced through the fangs by the palatine muscles. If a fang is broken off, it will be replaced by the next in a row

TABLE 44.1 *Crotalus* Species

US Rattlesnakes–Genus *Crotalus*:
  Timber rattlesnake (Canebrake)—*Crotalus horridus*
  Eastern diamondback—*Crotalus adamanteus*
  Western diamondback—*Crotalus atrox*
  Prairie rattlesnake—*Crotalus viridis*
  Mojave rattlesnake—*Crotalus scutulatus*
  Rock rattlesnake—*Crotalus lepidus*
  Black-tailed rattlesnake—*Crotalus molossus*
  Red diamond rattlesnake—*Crotalus ruber*
  Speckled rattlesnake—*Crotalus mitchellii*
  Sidewinder rattlesnake—*Crotalus cerastes*
  Tiger rattlesnake—*Crotalus tigris*
  Twin-spotted rattlesnake—*Crotalus pricei*
  Ridge-nosed rattlesnake—*Crotalus willardi*
  Western rattlesnake—*Crotalus oreganus*

TABLE 44.2 *Sistrurus* Species

Genus *Sistrurus* (Ground Rattlers/Swamp Rattlers):
  Massasauga—*Sistrurus catenatus*
    Eastern—Subsp. *catenatus*
    Western—Subsp. *tergeminus*
    Desert—Subsp. *edwardsii*
  Western pigmy rattlesnake—*Sistrurus miliarius streckeri*
  Carolina pigmy rattlesnake—*Sistrurus miliarius miliarius*
  Dusky pigmy rattlesnake—*Sistrurus miliarius barbouri*

TABLE 44.3 *Agkistrodon* Species

US Copperheads and Moccasins:
  Northern copperhead—*Agkistrodon contortrix mokasen*
  Osage copperhead—*Agkistrodon contortrix phaeogaster*
  Southern copperhead—*Agkistrodon contortrix contortrix*
  Broad-banded copperhead—*Agkistrodon contortrix laticinctus*
  Trans-Pecos copperhead—*Agkistrodon contortrix pictigaster*
  Eastern cottonmouth—*Agkistrodon piscivorus piscivorus*
  Florida cottonmouth—*Agkistrodon piscivorus conanti*
  Western cottonmouth—*Agkistrodon piscivorus leucostoma*

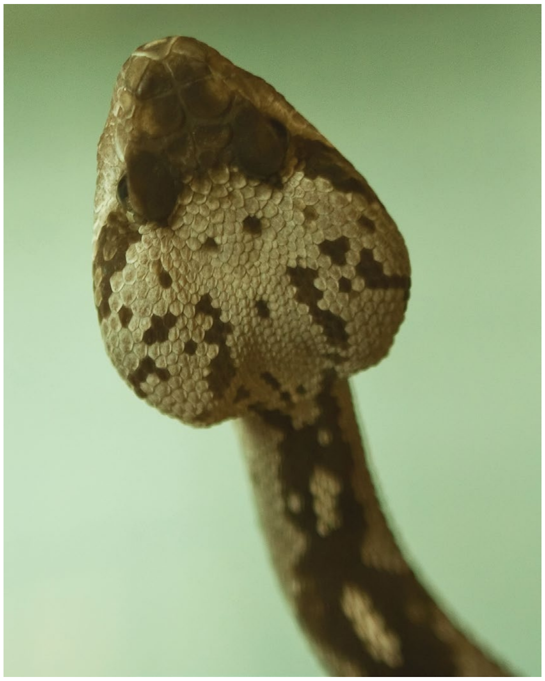

FIGURE 44.2 Pit vipers (i.e., genera *Crotalus*, *Sistrurus*, and *Agkistrodon*) are morphologically distinguished by elliptical pupils and a triangular head.

of "proto fangs." Any clothing may limit the amount and depth of envenomation. The purpose of the venom is to immobilize or kill the prey and begin digestion.

Snake Venom Composition and Consequences

Pit viper venoms are complex, with up to 50 different proteins and enzymes identified. Over 90% of the dry weight of venom is proteinaceous in nature. Although it is common to classify the venoms as neurotoxic or digestive in nature, all snakes have varying compositions of venoms. The Crotalids have a higher percentage of digestive/enzymatic type proteins than the Elapids, which contain a higher percentage of neurotoxins. Common enzymes are phospholipases, metalloproteases, collagenase, and hyaluronidase (Table 44.4). These peptides and polypeptides act by damaging vascular endothelium and other cellular membranes. Compliment is activated, fibrin is degraded, and platelets are activated. The increased permeability of the membranes leads to peripheral and pulmonary edema, hemorrhage, and hypotension. L-amino acid oxidase splits fibrinogen, contributing to the induction of disseminated intravascular coagulation (DIC). The Elapids contain a higher percentage of proteins that block acetylcholine receptor sites. This can lead to dysphagia, slurred speech, seizures, coma, and death. Despite the very high toxicity of coral snake venom, only one fatality has been recorded in the United States in the past 50 years.

Snakebite Management

By far the most critical step in management of snakebite is identification of the offending species. Most snakebites are nonvenomous and require no treatment. Most bites, such as those of copperheads and pigmy rattlers, are almost always self-limiting and require little more than observation. Others, such as bites from the diamondback rattlesnake (Fig. 44.3) and Mojave rattlers, can require intense medical management and occasional surgical intervention; rarely, they may even cause death. Identification of the species by the patient is notoriously invalid; however, a detailed description of the offending snake should be taken. In the United States and Canada, the only snake where color is useful in identification is the coral snake—"red and yellow kill a fellow, red and black venom lack" (Fig. 44.4). Note that this saying is true only in North America; there are venomous coral snakes in Central and South America that have red bands touching black bands. Other clues, such as geography and topography (proximity to water), can also at least help with identification of the genus. All snakebites should, at least initially, be considered an event with potential morbidity and possible mortality. Because snakes are cold-blooded animals, snakebites generally occur in the warm months, with an increase in incidence in the spring and fall. Most snakebites occur in young males, *with up to 60% of bites occurring in victims who were deliberately provoking the snakes.*

Field Treatment of Snakebites

The initial treatment of snakebite begins with first aid. Although identification of the snake is important, one should not risk a

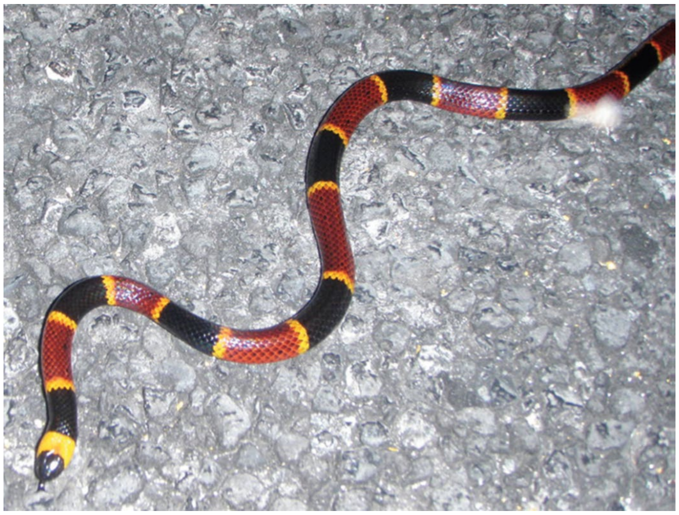

FIGURE 44.4 In North America, the only snake where color is useful in identification is the coral snake.

second bite to try to catch the snake. Do not delay treatment while looking for the offending reptile. Do not try to handle a dead snake directly because a reflexive bite can occur. Remove any jewelry or tight clothing from the affected extremity. Initial first aid on the scene should involve immobilization and splinting in a functional position. There are no data to confirm this will limit the spread of venom, but it will be more comfortable. The application of ice or heat seems to have little effect on results. Limit exertion, particularly extended ambulation in lower extremity bites.

When evaluating the snakebite victim, it is important to document both local and systemic signs and symptoms. Vital signs should be recorded and repeated at intervals guided by the clinical response. Pain, edema, and erythema at the site are common. Secondary symptoms include muscle twitching, perioral paresthesia, and a metallic taste in the mouth.

The wound should be cleansed, and the location of the puncture sites should be documented. The distance between the two fang marks is related to the size of the snake. In countries where a rapid venom identification kit will be used to swab the wound (e.g., Australia and Papua New Guinea), do not wash the wound. In other areas, gentle cleaning is acceptable. The application of pressure bandages—specifically, a constrictor band—is species specific. In countries where systemic neurotoxicity is more likely than necrosis (e.g., an Elapid bite in Australia), a pressure bandage or constrictor band should be considered and placed between the wound and the heart at approximately 55 mm Hg. This has been demonstrated to reduce systemic toxicity in an animal model.[1] However, in the United States, where the envenomation is most likely to be from a Crotalid, the application of a constrictor band is likely to result in concentration of the venom in the extremity, with increased necrosis and local enzymatic injury. It is probable that if there is no pain or erythema by the time the patient arrives in the emergency department, no envenomation has occurred. The patient should be promptly brought to appropriate medical care—if possible, a center with experience in management of snakebite.

Avoidable Treatments for Snakebites

Several historical treatments should specifically be avoided. Do not massage the wound, and particularly, *do not incise the wound.* Incision and suction, previously advocated for decades, have not been recommended since 1980. A surgical incision in the field by a nonsurgeon can possibly involve vessels, tendons, and nerves and increase morbidity, and only a small amount of venom can be extracted with suction. Also, avoid ligation cryotherapy, which is associated with a high rate of amputation. Creative attempts at treating envenomation have even included the use of electrical current to neutralize the venom. The use of current from the generator of an outboard motor and an automotive battery has even been attempted. As innovative and entertaining as these efforts may be, there is no improved outcome. The TASER or conductive electrical weapon (stun gun) is a small handheld device that produces a very high voltage with a low current. It is used primarily by law enforcement agencies to temporarily immobilize attackers. A group of physicians practicing in Ecuador reported a series of 34 patients in letters to the editor of *The Lancet* in which a modified stun gun was used to treat snakebites. They claimed an immediate improvement with no mortality. The snakebites were most likely from *Bothrops atrox*—the fer-de-lance—a pit viper. Unfortunately, this reported treatment was not a controlled study. Several animal studies have since proven electrical shock therapy to be ineffective in snakebite.

Hospital Evaluation and Treatment of Snakebites

Once in the emergency department, if not already performed in the field, intravenous access should be obtained. Marking the area of ecchymosis can help the clinician follow the progression of the envenomation (Fig. 44.5). Swelling in the affected digit or limb should be measured (circumference) and followed closely. The amount of local tissue destruction is an accurate marker of the degree of envenomation. Laboratory evaluation should include a complete blood count (CBC) with platelet count, prothrombin time (PT), partial thromboplastin time (PTT), creatine phosphokinase (CPK), fibrinogen level, blood urea nitrogen (BUN), creatinine, and urinalysis.

Up to 30% of Crotalid envenomation will show an abnormality in the coagulation profile, although clinical bleeding is exceedingly rare. In Lavonas's (2004) review of 400 copperhead (Fig. 44.6) bites from the Carolinas, no hypotension, respiratory failure, or deaths occurred.[2] Eight patients did have laboratory abnormalities, but none developed bleeding complications. However, in a severe envenomation by one of the larger rattlesnakes, diffuse capillary leakage can lead to pulmonary edema, hypotension, and shock. A consumptive coagulopathy may rapidly develop. In the rare patient that develops clinical bleeding, such as hemoptysis, intracranial hemorrhage, or gastrointestinal bleeding, correction of the coagulopathy should be undertaken with appropriate blood products. Antivenom should be given to these patients as initial therapy. Do not routinely treat

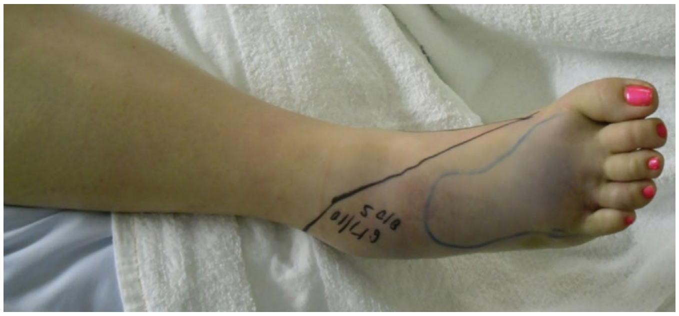

FIGURE 44.5 Progression of envenomation being monitored using serial skin marking.

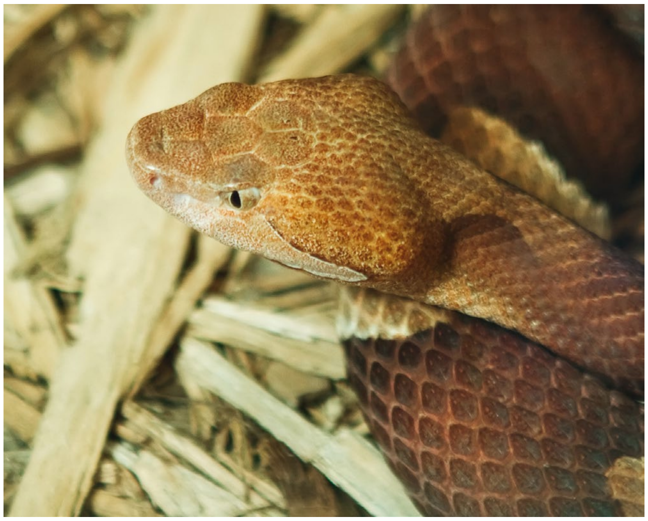

FIGURE 44.6 Copperhead, from the *Agkistrodon* genus, bites account for many of the treated snakebites in the United States.

thrombocytopenia or severe coagulopathy in the absence of bleeding. Coagulopathy can recur up to 2 weeks later.

Such patients may bleed spontaneously from any site. Acute renal failure may result from nephrotoxins as well as myoglobinuria. An electrocardiogram, or at least continuous cardiac monitoring, should be considered. Tetanus toxoid should be administered. If there appears to be no evidence of envenomation, the patient may be observed in the emergency department for several hours and discharged home. Although several series have noted that observation alone is an appropriate treatment of *Agkistrodon* (copperhead and moccasin) bites,[3,4] extrapolation of these data to rattlesnakes could be misleading. In the rattlesnake bite victim with a moderate or severe envenomation, early use of antivenom is appropriate and should be strongly considered (see later). In locales, such as Australia, where there is a preponderance of Elapid envenomations, the observation time should be extended because local skin changes may be minimal. With evidence of envenomation, general recommendations are for admission to a monitored bed in the hospital for observation and possible intervention for at least 24 hours.

Although there are a number of snakebite severity indices (grading systems) published, a modification of the simple system proposed by Dart in 1996 is probably the most useful.[5] A grade 1 envenomation is limited to the immediate bite site; a grade 2 envenomation extends on to less than a full extremity and may have non–life-threatening symptoms such as nausea, vomiting, mild tachycardia, and mild hypotension. A grade 3 envenomation involves more than an extremity and includes systemic signs such as severe hypotension/tachycardia, blood dyscrasias, or clinically significant clotting abnormalities. Although enzyme-linked immunosorbent assays (ELISAs) have been developed that can directly measure serum venom antigens as well as identify the offending snake, clinical applicability of these types of tests is limited.

Steroids have no benefit in humans, although these are often used by veterinarians. Steroids do have a role in treating the infrequent acute allergic reaction as well as delayed-onset serum sickness that may occur after the use of sheep-derived antivenom, as noted later. The prophylactic use of antibiotics has been evaluated by several studies and does not seem to reduce infection rates.[6] Infection after snakebite is surprisingly uncommon, and although patients are often given an antibiotic, there is no good clinical evidence for their use. Although many patients will have erythema, edema, and tissue necrosis and will appear infected, these are usually sterile; culture-proven infection occurring after snakebite should be treated appropriately. Culture of organisms in the mouth of the rattlesnake includes *Pseudomonas, Enterobacteriaceae, Staphylococcus,* and *Clostridia*. If the species is a coral snake or a nonindigenous Elapid, the administration of cholinergic agonists should occur at the first sign of symptoms. Calcium infusion may reduce the onset of seizures.

Antivenom Administration for Crotalid Envenomation

Certainly, the most controversial decision point in management of snakebite is the administration of antivenom. Although hundreds of antivenoms are available worldwide for various species, for all practical purposes in North America, the envenomation is limited to Crotalids. Snakebite by coral snakes is uncommon in North America, and although the venom is exceedingly toxic, the treatment is only supportive because antivenom is no longer available in the United States for coral snake bites. Cranial advancement of the area of ecchymosis at a rate greater than 10 cm per hour is generally considered an indication for initiation of antivenom therapy.

Before 2000, the primary antivenom available in the United States for the bite of a Crotalid was a hyperimmune serum produced by envenomation of horses. Its use was associated with a high incidence of side effects: anaphylaxis, hypersensitivity, and delayed serum sickness. In 2000, CroFab (Crotalidae Polyvalent Immune Fab [Ovine]) was introduced, obviating the use of now-unavailable horse serum products. This is now complemented by another purified product—ANAVIP. CroFab is composed of small Fab fragment antibodies, whereas ANAVIP is made from larger V-shaped F(ab')2 fragments. ANAVIP has a much longer half-life. This may result in a lower incidence of late coagulopathy. Note that the Crotalidae Immune F(ab')2 antivenom is of equine origin and may be problematic in those patients with horse allergies. A detailed review of antivenom therapy for pit vipers is provided by Weinstein.[7]

CroFab is truly an elegant drug. It is produced by immunizing sheep with the venom from the western diamondback rattlesnake *(C. atrox),* the eastern diamondback *rattlesnake (C. adamanteus),* the Mojave rattlesnake *(Crotalus scutulatus),* or the cottonmouth water moccasin *(Agkistrodon).* The monovalent immunoglobulin from the sheep is prepared by fractionating the immunoglobulin from the serum, digesting it with papain, and then using ion exchange and affinity chromatography to separate the Fab fragments specific to each species. The Fc portion of IgG is generally thought to be responsible for high rates of hypersensitivity and serum sickness seen with the horse serum product developed by Wyeth in 1954, and hence this ovine (sheep) version is generally considered safer. The four different monospecific antivenins are then mixed (Table 44.5). In a murine model, there is good antigenic crossover in treating other North American Crotalid envenomations.

The use of CroFab to treat Crotalid envenomation is somewhat controversial, primarily because of the cost-benefit ratio. The cost of this drug is a significant factor, with wholesale prices of up to $3200 per vial in 2023. Certainly, any patient with life-threatening symptoms should immediately be given four to six vials of the antivenom.[8] Treatment is not based on the body mass of the patient because the antivenom neutralizes the poison that is injected; this will vary with each envenomation. The lyophilized powder is reconstituted with 18 mL of normal saline, followed by dilution in 250 mL. Each dose is given over 1 hour. It is thought that venom is rapidly tissue bound; therefore, the earlier the antivenom can be given, the more likely a favorable response. The packaging information states that treatment should begin within 6 hours of the bite.

If one can ascertain that the snake is one of the less virulent types (*Agkistrodon* or *Sistrurus* species), the patient can usually be treated without the use of antivenom. However, in the patient with a deteriorating clinical condition, antivenom treatment should always be given. Repeated dosing should be given until clinical stability is achieved, although this is highly unlikely after 30 to 40 vials. The patient should be monitored for recurrence of symptoms and retreated if necessary. CroFab has an estimated half-life of 12 to 23 hours.

TABLE 44.5 **Components of Antivenom—CroFab**

Antibodies	LD50 Neutralizing Units
Crotalus atrox (western diamondback)	1350
Crotalus adamanteus (eastern diamondback)	800
Crotalus scutulatus (Mojave rattler)	5210
Agkistrodon piscivorus (cottonmouth water moccasin)	460

CroFab has been used extensively in children as young as 14 months, although there are beginning to be reports of overuse of CroFab in both children and adults. A special consideration is in the use of antivenom in pregnant patients. Certainly, coagulopathy could be lethal to the mother and fetus, but there have been limited reports of use of CroFab in pregnancy. Reports of fetal loss of up to 20% are noted in the worldwide literature with snakebites of a variety of species. This seems to be improved with the use of antivenom.[9] Certainly, the risk-benefit ratio must be carefully weighed, but the general recommendation is to treat pregnant patients with CroFab when indicated.

Consequences of Antivenom Administration for Snakebites

Immediate adverse drug reactions to CroFab will occur in 6% to 8% of patients. This may be related to the rate of infusion, although at least one study from Sri Lanka showed no difference in severe hypersensitivity reactions when the antivenom was over 20 minutes versus IV infusion of 2 hours. Although anaphylaxis would occur in up to 50% of patients treated with the older equine antivenin, it is a lesser occurrence with CroFab—up to 14% of patients. It should be treated aggressively when it occurs: The antivenin infusion should be stopped, and a combination of antihistamines (diphenhydramine), epinephrine, and steroids should be administered, depending on the severity of the response to anaphylaxis. The airway should be assessed and secured if necessary. Appropriate volume resuscitation should be instituted. Steroid dosing ranges from a single 125-mg intravenous bolus of methylprednisolone to short-course prednisone pulse dosing (60 mg daily for 5 days). Serum sickness will occur in 13% to 16% of patients treated with ovine antivenom (CroFab), certainly less common than with the older Wyeth equine antivenom.

Serum sickness is a type III hypersensitivity reaction in which soluble antigen–antibody complexes are deposited diffusely in the presence of antigen excess. Symptoms such as urticaria, itching, nephritis, and arthralgia can occur for weeks after the infusion. The treatment for serum sickness is a pulse of corticosteroids tapered over 7 to 14 days. There is no question that the purified ovine antivenins (CroFab) and ANAVIP (Crotalidae immune F[ab′]$_2$ [equine]) are much safer than the older horse product.[10] ANAVIP (Table 44.6) may be a better choice for several reasons: It is less expensive, has a longer half-life, can be stored at room temperature, and can be reconstituted more rapidly. Each CroFab vial costs about $3198, with 4 to 12 vials usually given, whereas ANAVIP costs $1220 with a starting dose of 10 vials. Whereas CroFab has a half-life of about 15 hours, ANAVIP has a half-life of about 133 hours—therefore, theoretically lessening the need for redosing. However, a recent publication indicates that in patients bitten by rattlesnakes, more ANAVIP was used, and more redosing was required.[11]

The decreased toxicity of modern antivenom has led to some indiscriminate and increasing usage in emergency departments across the country; there is at least one report of effective use of antivenom after significant delay. Thus is the conundrum—there are certainly snakebites that initially appear innocuous that later become life threatening. This has led physicians in the emergency room to overtreat large numbers of patients who do not require therapy; this is why it is so important that every attempt be made to identity the offending species. In a recent study, up to 84% of pit viper envenomations were treated with antivenom.[12] The reason for the high usage may be medicolegal because it is certainly not to reduce mortality, but in some cases, it may reduce morbidity. It should be recognized that the vast majority of snakebite victims will recover uneventfully with only supportive treatment. Each patient must be individually clinically evaluated, and antivenom use should be limited to those in whom the potential benefits outweigh the risk of side effects.

Agkistrodon piscivorus (water moccasin)	61

The Role of Surgery in Snakebites

The use of surgery in the management of snakebite has a limited role. Although historically, snakebite has been treated with various surgical procedures, it should be in an unusual patient in whom more than simple debridement is needed. The technique of crosscut and aspiration of the puncture sites was used for decades, but this is no longer recommended. Several studies have shown the limitations of this practice. In dogs, up to one-half of the venom can be removed, but only if incision and suction are begun within 3 minutes. In rabbits, up to 37% of antivenom can be removed. However, in human studies, only about 11% of the venom may be removed. It is rapidly bound to tissues and is difficult to remove by suction. Both partial and radical surgical excision of the involved bite area have likewise been attempted, with no proven benefit. A not-uncommon finding is a local cytolytic response (Fig. 44.7) that produces a hemolytic bulla and requires debridement (Figs. 44.8 and 44.9). Actual tissue loss occurs in 7.8% of rattlesnake bites and 3.8% of copperhead bites. These injuries can be expected to heal by secondary intention with a satisfactory cosmetic response (Fig. 44.10).

Another use of antivenom is in the patient with impending compartment syndrome. The great majority of snakebites deposit venom in the subcutaneous tissues, not subfascial. It can sometimes be difficult to differentiate a swollen, painful extremity from a true compartment syndrome. When in doubt, compartment pressures should be measured. With rising pressures (greater than 30–40 mm),

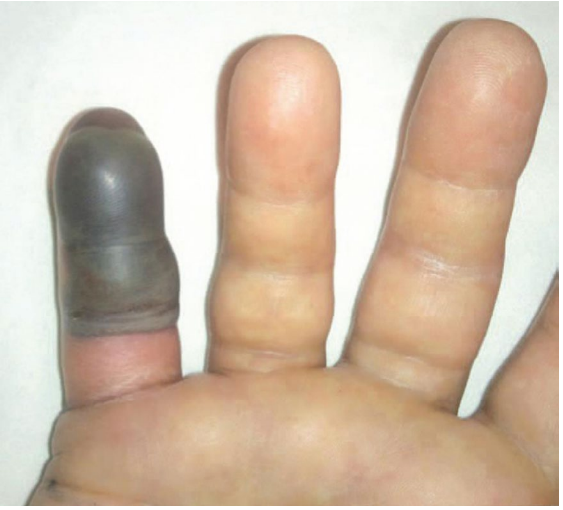

FIGURE 44.7 Snakebite resulting in local cytolytic response with hemolytic bulla.

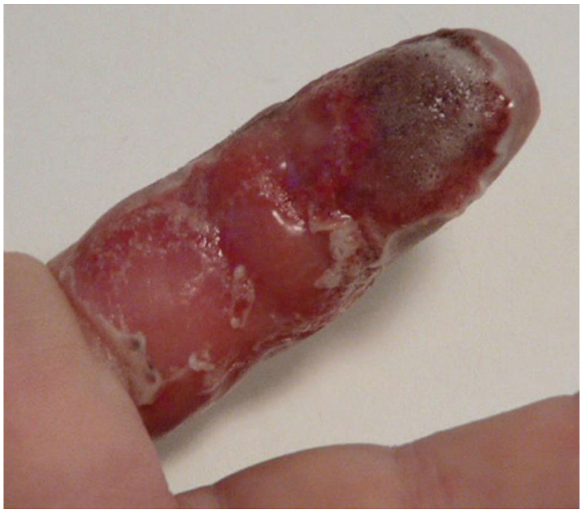

FIGURE 44.8 Snakebite requiring debridement.

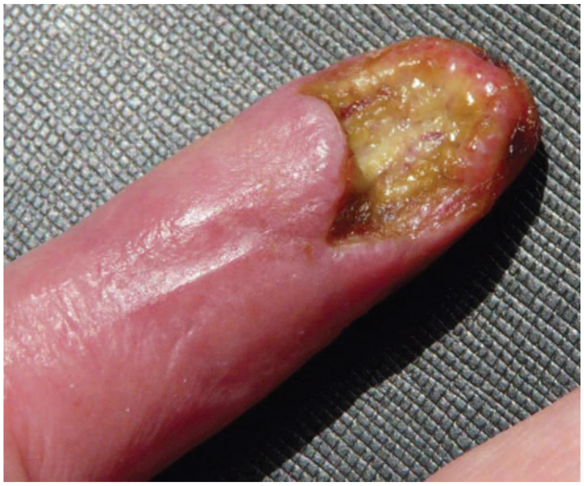

FIGURE 44.9 Another example of a snakebite requiring debridement.

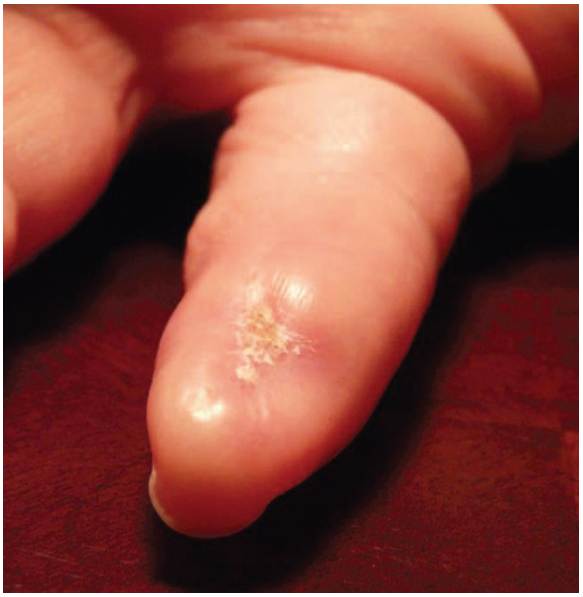

FIGURE 44.10 Healed snakebite.

antivenom therapy should be initiated (or repeated). With failure of response to adequate dosing of antivenom, appropriate surgical fasciotomy can save extremities. Prophylactic fasciotomy has no role in treatment. Stewart et al. at the University of Texas Health Science Center in San Antonio have extensive experience with rattlesnake bites.[13] They have randomized animals to receive an intracompartmental injection of venom from the western diamondback rattlesnake. The animals received fasciotomy with debridement alone, antivenom alone, or antivenom with fasciotomy and debridement. Antivenom therapy prevented muscle loss and improved survival. Surgery alone did not. It was noted that muscle that had been debrided would have survived if treated with antivenom alone. Fasciotomy may increase the severity of local tissue loss. When fasciotomy is required because of rising compartment pressures that do not respond to antivenom, consideration for postoperative negative-pressure wound therapy should be given.

Elapid Snake Epidemiology, Envenomation, and Treatment

As noted, there are only three species of Elapids in the United States—the eastern coral snake, the Texas coral snake, and the Arizona coral snake. The eastern coral snake *(Micrurus fulvius)* is found in the southeastern United States up to Kentucky and North Carolina. The Texas coral snake *(Micrurus tener)* is found west of the Mississippi across Arkansas, throughout Louisiana, and into eastern Texas. The eastern and Texas coral snakes inhabit forests and shrubbery. The Arizona coral snake *(Micruroides euryxanthus)* is found in the desert climates of the southwestern United States into Mexico. Coral snakes are more active at night and hide under ground cover. Their behavior is elusive, and they will generally try to flee when disturbed.

This family of snakes has a common feature—bilateral upper maxillary fangs that are fixed into position and angled down and back. The fangs are grooved for instillation of the venom, which is predominately a neurotoxin. The snakes are oviparous (lay eggs) and have round pupils. Their head is flat, with a smooth tapered tail and, of course, no rattles. They have characteristic coloration, which is mimicked by several other nonvenomous species (such as the king snake and the scarlet king snake) in an evolutionary phenomenon referred to as *Batesian mimicry*. Although the North American coral snakes are relatively small (less than 5 ft), some Elapids from other continents are very large; the Black mamba is 14 to 15 ft, and the king cobra can be up to 18 ft and weigh 25 lb. Although nonnative Elapid bites have a substantial risk for death, only one known death from a coral snake has occurred in the United States since 1967 (Bonita Springs, Florida, 2006).

The bite of an Elapid is likely to produce much less tissue injury than the bite of a Crotalid. There may be minimal pain. Envenomation may result in immediate neurotoxicity (within 15–30 minutes in the case of the mamba or Australian brown snake) or be delayed (2–5 hours with coral snakes). There is no longer any antivenom available for North American coral snakes, but local zoos and other countries may be able to provide antivenom for more exotic *Elapidae*. First aid should involve a compression bandage over the wound. The poison generally spreads by lymphatics; therefore, field compression to occlude lymph flow at the site of envenomation can slow toxicity. Symptoms will be related to the neurotoxicity—confusion, muscle spasm, nausea, vomiting, and dizziness. Blurred vision and difficulty with speech will occur. Finally, respiratory paralysis of the diaphragm occurs, with resultant death. Cardiovascular and pulmonary support is essential to salvage patients who progress to this state.

It should be noted that venom of an Elapid is incredibly toxic. Micrurus venoms contain a complex mixture of proteins that includes presynaptic phospholipase A2 neurotoxin and postsynaptic α-neurotoxin. The treatment should include neostigmine in the regimen. Deaths are usually from respiratory failure. The Taipan and Belcher sea snakes have an LD50 in mice of as little as 0.025 mg/kg of venom. Any suspected Elapid bite should be managed with the possibility of rapid demise of the patient. If the bite is of a nonnative Elapid, antivenom (if it can be found) should be administered promptly at the first sign of clinical demise. Death rates for untreated nonnative Elapids vary from 20% to 30% for cobras to nearly 100% for the mambas. Antivenom for exotic snakebites may be obtained from the local zoo or through zoos' national organization—the Association of Zoos and Aquariums (http://www.aza.org/antivenom-index)—or through the American Association of Poison Control Centers (1-800-222-1222, or visit http://www.poisonhelp.org). In the absence of coral snake antivenom, care remains supportive.

VENOMOUS LIZARDS

There are two venomous lizards in North America: the Gila monster *(Heloderma suspectum)* and the Mexican beaded lizard *(Heloderma horridum).* Both species have heavy bodies with large heads. The Gila monster is found in the southwestern United States, ranging primarily in Arizona and extending into southeastern California, southwestern Utah and New Mexico, and northern Mexico. There are two subspecies: the banded Gila monster (Fig. 44.11), which is found in the northern portion of the habitat, and the reticulated Gila monster, which exists in the southern portion of the range. The Gila monster is the largest lizard in the United States, with a length of up to 56 cm. The Gila monster has generated substantial lore in the southwestern United States because of its characteristic appearance and apparently fetid breath. It lives below ground and spends most of its life in or near its burrow. It is primarily seen in the spring, in the morning hours during breeding season. It has powerful jaws, and the bite is characterized by the tendency to hang on, with the animal being difficult to dislodge. The Poison Control Center reported 105 Gila-to-human bite-related calls from 2000 to 2011; 40% were seen in a hospital, and 16% were admitted, about one-third to an intensive care unit (ICU). There were no deaths.[14]

The Gila lizard has eight labial glands on either side of the lower jaw. The venom is secreted into the floor of the Gila monster's mouth, where it is wicked into the victim via grooved lower canine teeth. Envenomation is limited, and deaths are virtually unknown. The morbidity is usually secondary to local effects from the toxins present: serotonin, phospholipase A, amine oxidases, hyaluronidase, and proteases. These produce pain at the site that usually resolves in less than 24 hours. Hypotension, coagulopathy, and myocardial infarction have been reported. Nausea and vomiting can occur. Malaise may persist for several days. Recent study has shown a similarity between the venom of Gila monsters and monitor lizards (*Varanid* species). This shows neurotoxins blocking channels of sodium and calcium ion transport as a mode of paralysis. The patient should be admitted for observation, and a low threshold for surgical exploration/debridement is given because the teeth often shed into the bite and can serve as a nidus for infection. The Mexican beaded lizard is found from Sonora to Guatemala and is represented by four subspecies. They are larger than the North American Gila monster, with a maximum size of up to 91 cm. They have similar venom as the Gila monster, and bites should be managed in a supportive fashion. There is no antivenom available for Gila monster bites.

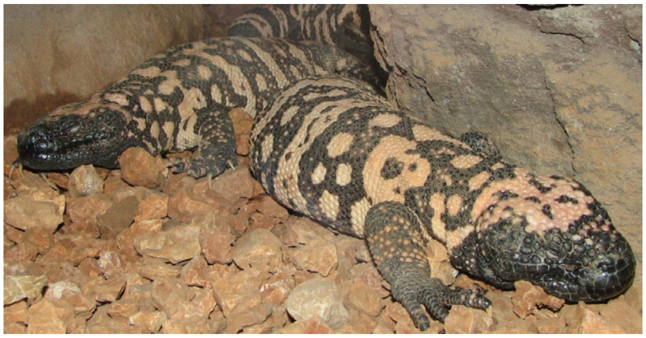

FIGURE 44.11 The venomous lizard, the banded Gila monster, *Heloderma suspectum*, which is found in the southwestern United States.

INSECT BITES AND STINGS

Although the bite of a venomous snake will certainly draw more attention in the emergency department, in fact, insects kill many more Americans (greater than 100 deaths per year) than snakes (about 5 deaths per year). Although most of these deaths are from anaphylactic reactions, some are from overwhelming envenomation, particularly from stings of the Africanized honeybee (the "killer" bee).[15] Most of the treatment recommendations that follow are from expert opinion; few randomized trials have been performed.

Spiders

There are six genera of spiders in the United States that can produce painful bites, tissue necrosis, and rarely, death. These fall into three groups—the brown recluse (Fig. 44.12), the black widow (Fig. 44.13), and the hobo spiders. Spider bites are notoriously difficult to diagnose because the insects are often not seen, the bites are often painless, and numerous dermatoses mimic spider bites.

Brown Recluse

There are 13 species of *Loxosceles*, of which 5 have been known to produce tissue necrosis. Probably the species producing the most pathology is the brown recluse *(Loxosceles reclusa).* Envenomation by the hobo spiders *(Tegenaria agrestis)* produces a similar wound. The brown recluse is generally found in the southern states. Hobo spiders are found in the Pacific Northwest.[16] Bites from these two species generally are initially painless, and the victim may not recall

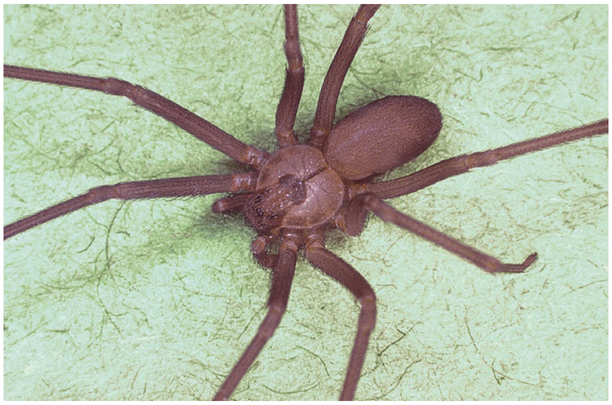

FIGURE 44.12 The brown recluse, *Loxosceles reclusa*, spider, nicknamed the *fiddleback spider*, *brown fiddler*, or *violin spider*. The characteristic dark line coming from its head looks like a violin, with the neck of the violin pointing to the rear of the spider.

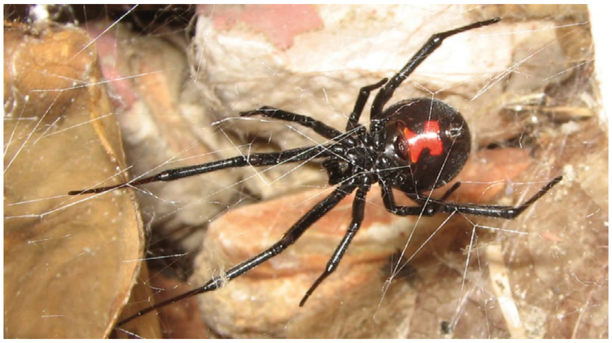

FIGURE 44.13 The black widow spider, with its characteristic red hourglass on the underside of the abdomen.

being bitten. Pain and erythema develop over the next 6 hours. The venom can produce a painful, necrotic, slow-healing wound over the next 48 to 72 hours. Two to 7 days after the bite, an eschar develops with surrounding soft tissue induration. The eschar can conceal an underlying tissue necrosis that can persist for months. The presence of adenopathy generally indicates another etiology for the necrosis.

Treatment is highly variable depending on the severity: Eschars can require extensive debridement leading to skin grafting and even amputation, or they can be left alone and allowed to heal spontaneously, often with a residual shallow crater from loss of fat and soft tissue. The venom is both hemolytic and cytotoxic. The enzyme that is thought to produce the “desmonecrotic arachnidosis” is sphingomyelinase D. The venom also contains hyaluronidase, lipase, arachidonic acid, and prostaglandins. Systemic symptoms occur in less than 10% of victims, more commonly in children. Rarely hemolysis, hemodynamic instability, and death have occurred.[17] Initial treatment should include analgesia, wound care, and tetanus prophylaxis. Antibiotics should be reserved for infection/cellulitis. Early debridement should be withheld. Consideration for oral dapsone therapy should be given. Dapsone is thought to work as an inhibitor of polymorphonuclear leukocyte chemotaxis. It has significant side effects and can produce hemolysis in glucose-6-phosphate dehydrogenase (G6PD)-deficient patients. Its use is somewhat controversial. It has been shown to reduce the size of the skin lesion and lessen the amount of surgical debridement, but these are not prospective studies. A controlled study in guinea pigs of dapsone, electroshock therapy, and no treatment showed some improvement with dapsone but none with the electrical therapy. Hyperbaric oxygen has been studied in rabbits and pigs and has failed to demonstrate significant improvement. A trial of hyperbaric oxygen, dapsone, and cyproheptadine in rabbits failed to show any improvement. Systemic steroids have not been shown to help. Initial surgical excision of the lesion has no clear benefit. Others have reported a favorable response to high-dose diphenhydramine, calling it “uniquely conservative,” but this has not been replicated. The same can be said for topical application with diethyl azelate (DEA), a plasma membrane fluidizer. Delayed excision of the area of necrosis with skin grafting can be necessary. Recurrent necrosis in the same site can return even years later.

Black Widow Spiders

There are 31 species of the genus *Latrodectus,* the black widow spider, of which 4 are found in North America. These are marked by a prominent red hourglass figure on the ventral aspect of the thorax. Although both the male and the female possess venom, only the bite of the female can penetrate human skin. The female is four times the size of the male. The female of the species is known for eating the male after mating, which may or may not occur. The bite may produce only minimal local symptoms, with only a small area of redness; a “target” appearance; or more dramatic erythema, induration, and purpura (Fig. 44.14). The venom contains α-latrotoxin, which is neurotoxic. This produces chest and abdominal pain, and the patient’s presentation may be confused as an acute surgical abdomen. Marked cramping and abdominal rigidity may be present. Fasciculations of facial muscles with periorbital edema, lacrimation, and blepharospasm may occur to produce *Latrodectus* facies. Hyperreflexia, paresthesia, cutaneous hyperesthesia, and nausea may also occur. Symptoms may occur within an hour and resolve over several days. A recent review of 59 cases from a single center in China reported that all patients were anxious, irritable, and restless, and they had difficulty breathing, with 71% having painful muscle spasm, sometimes called *latrodectism*.[18] The muscle spasm should initially be treated with benzodiazepines. Antivenom is available and should be considered in the very young and in other age groups simply to augment relief from pain, which usually lasts 3 to 7 days but sometimes for several weeks. The dose is 1 ampule given in 50 mL of saline, and the response can be quite dramatic and immediate. The antivenom is equine, and hypersensitivity testing should be done before giving the antivenom. A 1-mL test dose of horse serum is included with the antivenom for topical conjunctival testing. Calcium gluconate was often given in the past but is no longer recommended. Mortality is exceedingly rare.

Hymenoptera

More than 100,000 species of Hymenoptera exist. This includes the winged Hymenoptera, the *Apidae* family (honeybees and bumble bees) and the *Vespidae* family (yellow jackets, yellow hornets, white-faced hornets, and paper wasps), and the wingless Hymenoptera, the *Formicidae* family (fire ants, harvester ants, bulldog ants, and jack jumper ants). The venom injected by these insects is at least as toxic as that of the rattlesnake, but the volume is much less. The venom is primarily a hemolysin and neurotoxin.

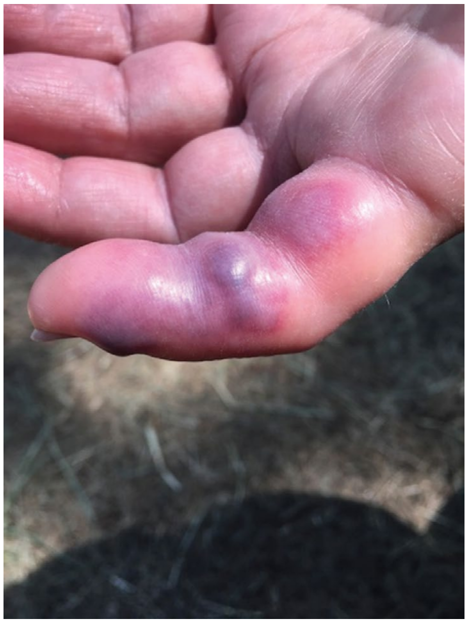

FIGURE 44.14 Erythema, induration, and purpura associated with a black widow bite.

Anaphylaxis is a common clinical problem produced by the envenomation. The incidence of systemic allergic reactions after a sting is currently estimated to be between 0.15% and 0.8% in children and up to 8.9% in adults.[19] The anaphylaxis is modulated by preformed IgE that activates mast cells, leading to massive histamine release. This leads to laryngeal edema, pulmonary edema, and cardiovascular collapse. This must be treated aggressively with IV diphenhydramine, epinephrine, and fluid resuscitation, as well as with management of the airway and supplemental oxygen. Most stings are mild, however, resulting in only dermal reactions—pain, erythema, and edema. The stinger should be removed, and ice should be applied to the site. Bees and some yellow jackets have a barbed stinger that, once inserted, injects the venom from a sac that is torn from the insect. This takes a few seconds, and if the stinger can be "flicked off" in the first few seconds, the amount of venom may be limited. Application of meat tenderizer might be of some benefit. Patients with a history of insect sting anaphylaxis should be given a prescription for an epinephrine pen and be considered for venom immunotherapy. This is almost 100% successful in desensitization but can take up to 3 years.

Killer Bees

Africanized honeybees (killer bees) are hybrids of the African honeybee and the European honeybee, the one commonly found in the United States. The Africanized honeybee was originally brought from Tanzania to Brazil in 1957, with the hope of better honey production. The bees have spread up through Central America, Mexico, and into southwestern United States. They are continuing to advance at about 100 miles/yr, with some evidence of slowing in more recent years. Africanized honeybees are indistinguishable from the European honeybee, so DNA (usually mitochondrial DNA) analysis is necessary to differentiate the subspecies. They are termed "killer bees" because of their increased aggressive traits. They show greater defensiveness of the hive, they have a bigger "alarm" area, and they deploy in greater numbers and will pursue perceived threats over much greater distances. Although their venom is of the same potency as the European bees, the number of stings received will usually be much greater. With more than 50 stings, nausea, vomiting, shock, hemolysis, rhabdomyolysis, coagulopathy, coma, and death may occur. Usually, most patients will just complain of pain, but delayed toxic reactions—over 6 to 48 hours—may also occur. It is recommended that any patient presenting with more than 50 stings be hospitalized and observed. Laboratory evaluation with coagulation studies, platelet count, and liver function studies should be obtained.

Fire Ants

Fire ants, *Solenopsis invicta*, are wingless members of the Hymenoptera order. They were brought to the United States from South America around 1918 and have spread throughout the southern United States (Fig. 44.15). The imported red fire ants appear to have been introduced on a ship through Mobile, Alabama. Shipments of infested nursery stock and other agricultural products, natural mating flights, floating wood on flood waters, and lack of natural enemies have contributed to their spread. There are now five times more ants per acre in the United States than in their native South America. Two species of imported fire ants now infect large areas of the Gulf Coast states. Fire ants aggressively attack

any perceived danger to themselves or their mound. Each ant can produce multiple stings. The venom is a dialkylpiperidine that induces the release of histamine from increased mast cell reactivity. The fire ant sting produces a sterile pustule, which does not usually require antibiotic therapy. Infectious complications can occur at the site and may be more common in patients with diabetes or immunocompromised patients. More than 80 fatalities have been reported from fire ant anaphylaxis, notably in Australia and the southern United States. The treatment is the same as with bee/wasp sting anaphylaxis. Fire ant venom shares at least four antigenic proteins with bees and wasps.

Scorpions

More than 1500 species of scorpions can be found worldwide. Only about 20 or 25 are considered dangerous. They are in the class Arachnida, close relatives of ticks, mites, and spiders. Scorpions prefer dry habitats but may be found throughout the southern United States. Scorpions are nocturnal, hiding during the day and becoming active at night. The scorpion's body has a five-segmented tail that can be arched over the back and becomes slenderer toward the end. On the end of the tail is the bulb-like poison gland/stinger. Between the last pair of legs are comblike structures called the *pectines*—sensory organs used to sense surface textures and detect prey. The venom toxicity varies greatly depending on the species, season, and age of the scorpion. Stings from dangerous species may cause paralysis, severe convulsions, cardiac irregularities, breathing difficulties, and death. In the United States, most scorpion stings are not life threatening and only result in local effects. In parts of Brazil, Mexico, North Africa, and Israel, however, the sting may be lethal. In Brazil, the mortality rate is as high as 12% for adults and 60% for children. In India, of 34 children admitted to a hospital for a scorpion sting, 14 had hypertension, 9 had acute pulmonary edema, 5 had a myocardial infarction, and 4 died. Antivenins are typically available in areas where dangerous species are found, either from a local zoo or state or university agricultural extension departments. Only one species in North America is particularly venomous—the Arizona bark scorpion *(Centruroides exilicauda)* (Fig. 44.16). The bark scorpion is relatively diminutive, reaching only an inch and a half at maturity. The sting produces a dramatic neuromotor syndrome and respiratory insufficiency. It has produced several deaths in the United States and hundreds in Mexico. Anascorp (an immune F[ab]2 equine antivenom) is now available for patients with systemic symptoms.[20] It (like CroFab) is very expensive (about $12,000 per vial in the United States—or $100 per vial in Mexico; 2013 prices for reference).

Centipedes and Millipedes

There are approximately 3000 species of centipedes in the world. They are arthropods with a single set of legs on each body segment. The front pair of legs is modified to deliver venom. One of the largest members of this class is the giant desert centipede *(Scolopendra gigantea)*. It can grow to 26 cm in length. Significant morbidity, including ECG changes and rhabdomyolysis, can occur from centipede bites, but death is exceedingly rare. The most common symptoms include erythema, swelling, and pain. Treatment is largely symptomatic, with reports of both ice and heat improving symptoms. There are approximately 7000 species of millipedes. They have two pairs of legs on each body segment. Millipedes do not have a mechanism to inject a venom but instead secrete an irritating liquid from pores covering their body. This can produce a superficial burn that is self-limiting. Only symptomatic therapy is indicated.

Asp Caterpillars

The asp is a venomous caterpillar found in the southern United States. It is the larval stage of the southern flannel moth *(Megalopyge opercularis)* (Fig. 44.17). It has the appearance of soft, furry ball, encouraging the unwary to touch it (also referred to as the *puss moth,* given its catlike appearance). The long hairs of the asp conceal shorter spikes that discharge venom. Typically, an intense throbbing and pain will occur almost immediately. Erythematous spots occur at the site of envenomation (erucism). Symptoms

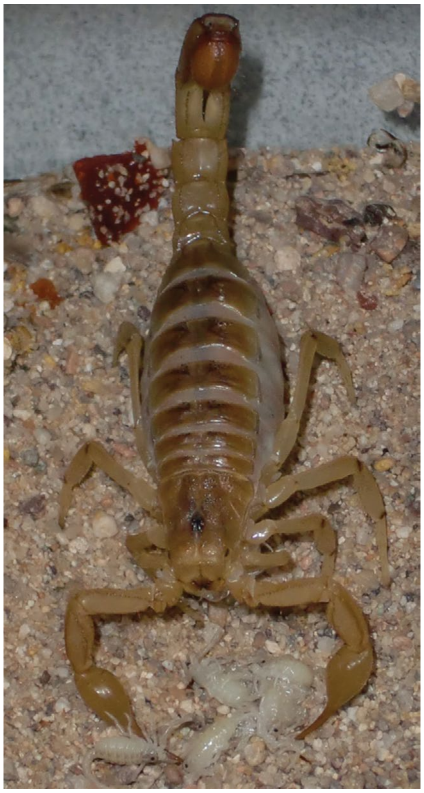

FIGURE 44.16 The venomous Arizona bark scorpion *(Centruroides exilicauda).*

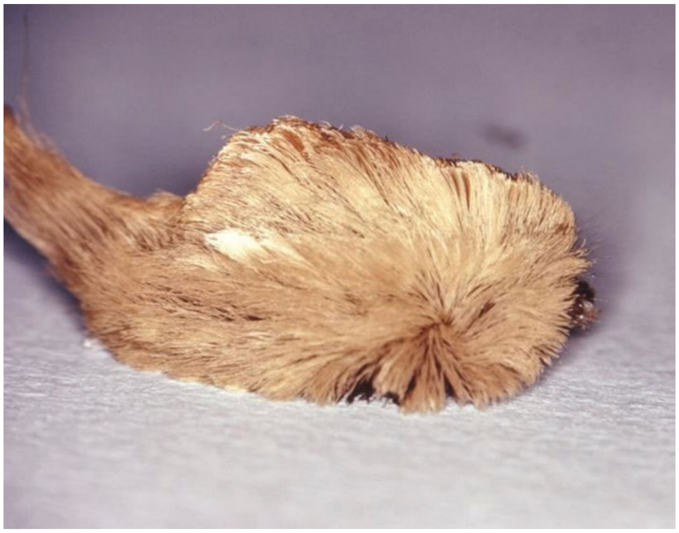

FIGURE 44.17 The long hairs of the asp caterpillar, also known as the *southern flannel moth* and *puss moth (Megalopyge opercularis),* conceal shorter spikes that discharge venom.

include headache, nausea, vomiting, and the development of lymphadenopathy. Chest pain occurs occasionally. Rarely, shock and respiratory distress have been reported. Death is exceedingly rare and is almost certainly because of a hypersensitivity reaction. A similar caterpillar found in South America—*Lonomia*—has a death rate of 1.7%. The initial treatment should be to apply adhesive tape and pull it off to remove the spines. Ice packs, NSAIDs, acetaminophen, and antihistamines may provide symptomatic relief. Intravenous calcium and steroids have been suggested as a treatment regimen.

ENVIRONMENTAL EXPOSURE

Hypothermia

Humans, like all mammals, will always attempt to maintain a constant body temperature despite changes in environmental temperature. Normal human body temperature is thought to physiologically vary between 36.1°C and 37.2°C. It also varies by body location: 37°C sublingually, 38°C in the rectum, 32°C at the skin, and 38.5°C deep in the liver; we tolerate poorly even minor deviations from these norms. Although humans have a remarkable capacity to dissipate heat by evaporating body water, our tropical evolutionary heritage has provided us with far less ability to cope with cold conditions. As a result, hypothermia can occur in a variety of clinical settings and from several causes (Table 44.7).

Hypothermia is present in humans if the core temperature drops below 35°C. Hypothermia is usually classified by temperature zones: mild (32°C–35°C), moderate (28°C–32°C), or severe (<28°C). *Primary* accidental (vs. intentional) hypothermia is defined as a decrease in core temperature that occurs because of overwhelming environmental cold stress, such as recreational misadventures that lead to cold-water immersion or prolonged environmental exposure. *Secondary* accidental hypothermia is triggered by, or at least associated with, underlying disease. Secondary accidental hypothermia occurs in patients with impaired thermoregulation, decreased heat production, or increased heat loss. These patients become cold despite only mild cold stress. The most significant risk factors are advanced age, mental impairment, and substance abuse (alcohol, primarily), although hypothyroidism, hypoadrenalism, trauma, and hypoglycemia are other risk factors. Chronic hypothermia develops in patients with impaired heat generation (i.e., the elderly and infirm) who live in unheated apartments, are under continual cold stress, and after a time, are found to have a chronically low temperature as if they have autoregulated to a new, lower-set core temperature.

From Perlman R, Callum J, Laflamme C, et al. A recommended early goal-directed management guideline for the prevention of hypothermia-related transfusion, morbidity, and mortality in severely injured trauma patients. *Crit Care.* 2016 Apr 20;20(1):107.

It is estimated that each year, about 1500 patients in the United States have hypothermia listed on their death certificate, although the exact incidence and associated morbidity and mortality remain poorly characterized. The 2015–17 death rate from accidental hypothermia per 100,000 in the United States is depicted in Fig. 44.18. This figure emphasizes the problem of hypothermia resulting from exposure in rural environments. An updated CDC report in 2020 confirmed that death rates attributed to hypothermia were higher in rural areas, such that among females, the death rate increased from 0.11 per 100,000 for those residing in large central metro areas to 0.40 for those in noncore, rural areas. Among males, the death rates were lowest for those residing in large central metro areas (0.29) and large fringe metro areas (0.24) and highest for those in noncore, rural areas (0.93). A multicenter review of 428 cases of accidental hypothermia reported an overall mortality rate of 17%, although other reports document mortality rates as high as 80%, primarily a result of infection and underlying illness. Matsuyama reported on the national Japanese registry of hypothermia experience of 537 patients with hypothermia, with an in-hospital death rate of 24.2%. From 1999 to 2011, a total of 16,911 deaths in the United States, an average of 1301 per year, were associated with exposure to excessive natural cold. The highest yearly total of hypothermia-related deaths (1536) was in 2010, and the lowest (1058) was in 2006. Most reported hypothermia-related deaths (67%) occurred in males, but the overall death rate is the same for both males and females. Notable is that deaths occur in all states, even those that generally are considered to have warm climates. Hypothermia-related deaths are reported by states with characteristically milder climates that experience rapid temperature changes and by western states that have high elevations and experience considerable changes from daytime to nighttime temperatures. In the United States, the greatest overall death rates caused by hypothermia are found in Alaska, New Mexico, Wyoming, and Montana.

The physiologic response to hypothermia is one of transitional changes, with few exact temperature-dependent responses (Fig. 44.19). Broadly speaking, the transition from a “safe zone” of hypothermia (in which physiologic adaptations to heat loss are working) to a “danger zone” of hypothermia (in which shivering is abolished, metabolism decreases, and heat loss is passively accepted) occurs between 33°C and 30°C. The initial effects of hypothermia mimic intense sympathetic stimulation, with tremulousness, profound vasoconstriction, tremendous increases in oxygen consumption, and acceleration of heart rate and minute ventilation. When core body temperature cannot be measured, a four-stage hypothermia classification based on vital signs and level of consciousness has been developed by Swiss

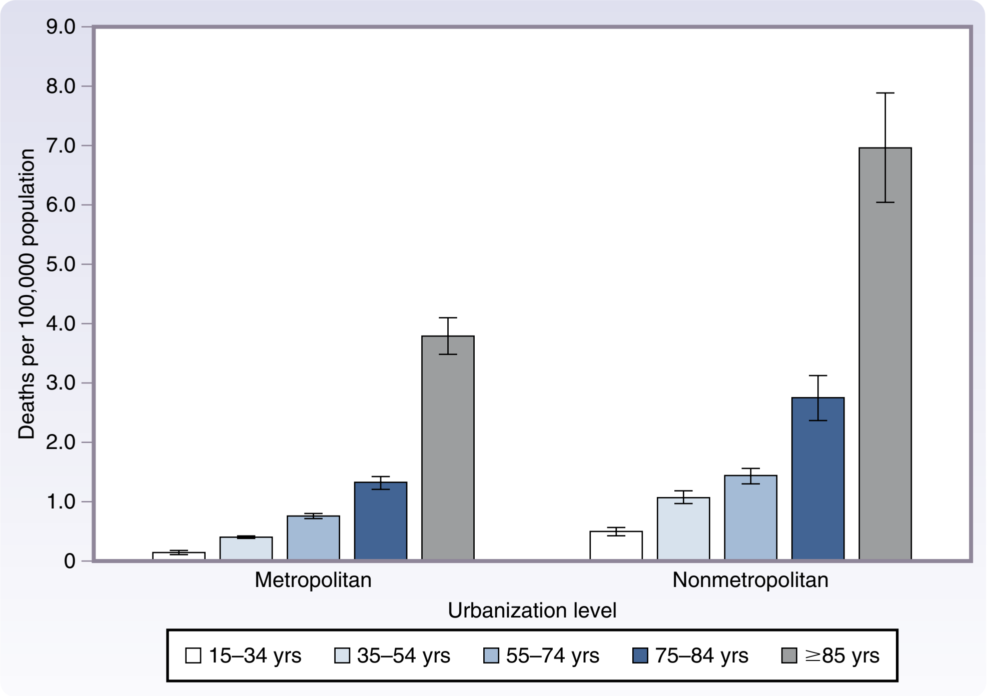

FIGURE 44.18 Death rates* attributed to excessive cold or hypothermia† among persons aged ≥15 years, by urbanization level§ and age. *Crude rate of deaths per 100,000 population; 95% confidence intervals indicated by error bars. †Deaths attributed to excessive cold or hypothermia were identified using the *International Classification of Diseases, Tenth Revision* underlying cause-of-death code X31 (Exposure to excessive natural cold) or multiple cause-of-death code T68 (Hypothermia). §Urbanization level is based on the Office of Management and Budget's February 2013 delineation of metropolitan statistical areas (MSAs), in which each MSA must have at least one urbanized area of ≥50,000 inhabitants. Areas with <50,000 inhabitants are grouped into the nonmetropolitan category. (From QuickStats: death rates attributed to excessive cold or hypothermia among persons aged ≥15 years, by urbanization level and age group—National Vital Statistics System, 2015–2017. *MMWR Morb Mortal Wkly Rep.* 2019;68:187.)

clinicians. It should be emphasized that the purpose of the Swiss clinical grading is to direct treatment in the absence of the ability to actually measure core body temperature, as well as to predict the risk of hypothermic cardiac arrest, so it should have its primary purpose in the austere or field care environment.

The most current modification of the Swiss staging system for hypothermia and risk of cardiac arrest is shown in Fig. 44.20. In this latest revision, shivering is not used as a stage-defining sign, although its presence usually means that the core temperature is >30°C, a temperature at which hypothermic cardiac arrest is unlikely. The estimated risk of cardiac arrest is based on accidental hypothermia being the only cause of clinical findings. If other conditions impair consciousness, such as asphyxia, intoxication, high-altitude cerebral edema, or trauma, the Revised Swiss System may falsely predict a higher risk of cardiac arrest. Be cautious with patients who remain "alert" or "verbal" but show signs of hemodynamic or respiratory instability (e.g., bradycardia, bradypnea, hypotension); they may be at a transitional stage with a higher risk of cardiac arrest.

The cardiovascular response to hypothermia begins with tachycardia but is followed by progressive bradycardia, which starts at approximately 34°C and results in a 50% decrease in heart rate at 28°C. Cardiac output initially increases with the tachycardia and then progressively decreases, with a concomitant fall in blood pressure. The conduction system is particularly sensitive to hypothermia: The PR interval, then the QRS complex, and finally the QT interval become progressively prolonged. As the temperature falls below 30°C, atrial fibrillation, bradycardia, and ventricular dysrhythmia become common, with asystole occurring at temperatures below 25°C.

Perhaps the most challenging management of an accidental hypothermia patient is the one with temperatures between 28°C and 32°C (Swiss stage 2) because these patients are prone to develop poorly perfusing arrhythmias, yet they often can be rewarmed with active external and environmental rewarming if such arrhythmias do not occur. Hence, gentle manipulation of such patients is required. Because palpating pulses or measuring blood pressure in cold, stiff, hypothermic patients is difficult, the presence of an organized cardiac electrical rhythm should be taken as a sign of life that contraindicates cardiopulmonary resuscitation (CPR) chest compressions, despite the absence of a palpable pulse. Such a rhythm may provide diminished but sufficient circulation in patients with severely reduced metabolism, and it is likely that vigorous chest compressions will convert this perfusing rhythm to fibrillation. Rewarming should occur with close monitoring of rhythm, pulse, and blood pressure. If cardiac arrest occurs (Swiss stage 3 or 4), extracorporeal cardiopulmonary bypass (CPB) or extracorporeal membrane oxygenation (ECMO) for perfusion and rewarming is indicated.[21]

Among patients with what is likely Swiss stage 4, those treated with ECMO or CPB have a reported survival rate without neurologic impairment of 47% to 63%, compared with 37% for similar patients treated without active core rewarming and oxygenation techniques. One report noted excellent long-term functional

Check for signs of life (pulse and, especially, respiration) for up to 1 minute. $^{\Delta}$The transition of colors between stages represents the overlap of patients within groups.

outcomes in 15 of 32 young patients successfully rewarmed with CPB. All patients were intubated and ventilated and had received ongoing cardiac massage during transportation, and all 15 survivors had documented circulatory arrest (ventricular fibrillation or asystole) and fixed, dilated pupils. The mean interval from discovery of the patient to rewarming with CPB was 141 ± 50 minutes; the mean temperature was 21.8°C ± 2.5°C. A report from Finland documents a 61% (14 of 23) survival to hospital discharge for adults undergoing CPB after a mean of 70 minutes of CPR after hypothermic arrest, primarily from cold-water immersion or exposure. A recent review of 18 studies in the literature and 286 hypothermic patients in cardiac arrest who underwent extracorporeal support documented a 37% survival rate, with 84% having good neurologic outcome.[22] Finally, the lowest recorded temperature from which a person has been successfully resuscitated after accidental or secondary hypothermia is 13.7°C.

Respiratory drive is increased during the early stages of hypothermia, but below 33°C, progressive respiratory depression occurs, resulting in a decrease in minute ventilation. This decrease is not usually a significant problem until temperatures below 29°C are reached. Occasionally, hypothermia results in the production of a large amount of mucus (cold bronchorrhea). This development predisposes to atelectasis and aspiration because ciliary action and the cough reflex are also depressed. Noncardiogenic pulmonary edema is also occasionally reported, especially in elderly patients and especially after prolonged periods of hypothermia.

The effect of core hypothermia on arterial blood gas interpretation warrants a comment. Arterial blood gas samples are typically warmed to 37°C before measurement. A nomogram of Severinghaus mathematical corrections is then used to estimate the blood gas values at the patient's actual body temperature. With each 1°C temperature drop, the PCO_2 decreases by 4.4%, and the PO_2 decreases by 7.2%. Gas solubility increases with decreasing fluid temperature; hence, the decrease in partial pressure is related to the increased solubility of gases in cold fluids and is not a result of a change in carbon dioxide content, oxygen content, or serum bicarbonate level. Clinicians often assume that the "normal" PCO_2 and PO_2 at 37°C are the values that should be attained at all temperatures. However, if normothermic end points for PCO_2 were attained in a hypothermic patient, they would have increased total-body CO_2 stores, which would manifest as a rising PCO_2 and a falling pH during rewarming. Likewise, attempts at increasing a Po_2 that reflects normal oxygen content at a lower temperature are also inappropriate. A far simpler strategy is to assess the blood gases at 37°C without temperature correction. Values that are normal and acceptable when reported at 37°C (without temperature correction) correspond to normal values and contents when "corrected" for hypothermic temperatures.

Temperature correction of blood gases for pH management is also unnecessary. The pH of water rises with cooling, causing the pH of blood to rise by 0.015 pH units/°C, without a change in bicarbonate content. Treating a patient with a temperature of 30°C with a pH of 7.40 instead of 7.47 fails to maintain the normal pH offset above the neutral point of water (relative alkalinity) and results in an acidotic cellular and chemical environment that has a multiplicity of effects on enzyme systems. Because blood with a pH of 7.40 assessed at 37°C is reported as having a pH of 7.47 when temperature corrected to 32°C, the simplest strategy when confronted with a patient with a temperature of 32°C is to assess the blood gas at 37°C only and to use the 37°C uncorrected pH value for management.[23]

The neurologic response to hypothermia is heralded by progressive loss of lucidity and deep tendon reflexes and, eventually, by flaccid muscular tone. Patients are often amnestic below 32°C, and between 31°C and 27°C, they usually lose consciousness. Pupillary dilatation and loss of cerebral autoregulation occur at temperatures below 26°C, and electroencephalography becomes silent at 19°C to 20°C. These findings, combined with an unobtainable pulse and apparent rigor mortis, may cause the patient to appear dead. It is important to remember that patients have been revived from core temperatures as low as 13.7°C, hence the saying "No one is dead until warm and dead."[24] An exception to this admonition probably includes the patient who has sustained an anoxic event while still normothermic and has a serum potassium level of greater than 10 mmol/L, although the Bernese criteria for trauma and hypothermia have picked a level of 12 mmol/L as being nonsalvageable.[25,26]

The role of hypothermia in brain death determination remains controversial. Brain death is a medically and legally accepted mechanism of death in the United States and worldwide. Yet significant variability in individual institutional policies regarding the determination of brain death occurs. In 2010 the American Academy of Neurology (AAN) issued guidelines on the determination of brain death, reaffirmed in 2023. A recent study examined how consistently 52 organ procurement organizations and 508 unique hospitals have adopted these guidelines, determining that among other variables in policy, only 181 of 228 policies (80%) required the absence of hypothermia (temperature $>$36°C) in brain death determination.[27] The World Brain Death Project was developed to achieve a consensus among professional organizations on determining brain death. A 2020 report recommended and suggested that determination of the clinical criteria for brain death should include a minimum core temperature of 36°C.[28]

In classic surgical physiology research, Moyer and Debakey showed that with hypothermia, reduction in blood pressure and cardiac output decreases glomerular filtration rate, but urinary output is maintained because of impairment in renal tubular Na^+ reabsorption (so-called "cold diuresis"). Vasoconstriction also results in an initial increase in central blood volume that prompts a diuresis. Ileus, bowel wall edema, depressed hepatic drug detoxification, punctate gastric erosions (Wischnewski ulcers), hyperamylasemia, and rarely, hemorrhagic pancreatitis are hallmarks of the intestinal response to hypothermia. Hypothermia inhibits insulin release and insulin uptake at receptor sites, making hyperglycemia a relatively common finding, especially at temperatures below 30°C. Exogenous insulin administration is unwarranted because it may result in rebound hypoglycemia during rewarming. Serum electrolyte changes are unpredictable, but serum potassium is often slightly increased in hypothermic patients because of renal tubular dysfunction, acidosis, and the breakdown of liver glycogen. Hypothermia also appears to affect endothelial cell adhesion molecule function, which may partially explain increased infectious complications in hypothermic patients. One study demonstrated that a drop of 1.9°C in core hypothermia triples the incidence of surgical wound infection after colon resection and increases the duration of hospitalization by 20%, leading to the now-standard perioperative checklist monitoring of body temperature during surgery.

Body temperature also has a significant effect on oxygen uptake. Oxygen consumption (VO_2) initially increases dramatically with any fall in body temperature. When involuntary muscle contractions in the form of shivering occur, oxygen consumption increases by threefold to fivefold. This process is inefficient because shivering produces heat near the surface of the body, causing most of the heat to be lost to the environment, with less than 45% being retained by the patient. As core temperatures fall to between 33°C and 30°C, shivering is abolished, and the patient will rapidly sink to ambient temperature.

The thermoregulatory drive is such a powerful one that it takes precedence over many other homeostatic functions. The resultant increase in oxygen use may result in anaerobic metabolism, acidosis, and significant cardiopulmonary stress. One study noted a 35% increase in oxygen consumption and a 65% increase in CO_2 production in postoperative patients after resolution of anesthesia, when the thermostatic drive reappeared. In another study, a core temperature decrease of as little as 0.3°C in postoperative patients was associated with a 7% increase in VO_2, and temperature reductions between 0.3°C and 1.2°C were associated with a 92% increase in VO_2, with proportional increases in minute ventilation. Shivering can be abolished with low doses of meperidine (Demerol). Ondansetron (Zofran, Zuplenz) will reduce postoperative shivering, but it is unknown if it is effective in primary hypothermia.[29] Further details of the specific organ system responses to hypothermia are beyond the scope of this chapter, but the interested reader is referred to several excellent in-depth monographs.[30]

Hypothermia in Trauma Patients

Mild hypothermia is very common after traumatic injury. The thermoneutral environment for humans is a humid and warm 28°C (82.5°F), like a tropical island. When ambient temperature falls below the thermoneutral temperature (i.e., the temperature at which no thermogenesis or heat dissipation is necessary), an increase in heat production is required to maintain a normal body temperature. Combustion is the only source of endogenous heat production, and this process requires an increase in oxygen use. After shock or injury, however, oxygen supplies are often limited, and further heat loss occurs owing to cold emergency department and operating room environments, cold fluid resuscitation, and open thoracic and abdominal cavities. Anesthetic and neuromuscular blocking agents that prevent the heat-producing shivering response further aggravate this. Thus, the occurrence of hypothermia in surgical or critically injured patients is most often a form of secondary accidental hypothermia.

One study found that 57% of trauma patients admitted to a Level 1 trauma center were hypothermic at some time and that temperature loss was most significant in the emergency department. Another study reported that the average initial temperature for 94 intubated major trauma victims was 35°C, with no seasonal variation. Of patients in this study, 66% were hypothermic on admission, 43% were mildly hypothermic (34°C–36°C), and 23% had temperatures below 34°C. Likewise, Jurkovich and Luterman reported that 42% of 71 adult trauma victims with an injury severity score (ISS) of 25 or higher had core temperatures below 34°C, and in 13%, the core temperature fell below 32°C.[31] Importantly, there were no survivors when core body temperature was below 32°C. Inaba[32] reported that of 118 patients requiring emergent surgery after traumatic injury, hypothermia ($<35°C$) was present in nearly 30% of patients upon presentation to the operating room, and a continued decrease in core temperature was associated with increased mortality. This mortality rose to 50% if temperature fell below 32°C. Both mortality rate and the incidence of hypothermia increase with higher ISS, massive fluid resuscitation, and the presence of shock, but controlling for these variables still demonstrates that the mortality rate of the hypothermic trauma patient is greater than that of the warm trauma patient. Although the mortality rate for moderate (28°C–32°C) degrees of primary accidental hypothermia is approximately 20%, moderate levels of hypothermia in trauma and critically ill patients are associated with a much higher mortality rate. Rutherford et al. reported that 9.4% of surgical ICU patients had a core body temperature less than 35°C; the mortality rate of the hypothermic trauma patients was 53%. In fact, compared with other patient populations, the mortality rate associated with hypothermia in the trauma victim is so high that the definition of mild, moderate, and severe hypothermia in the trauma patient warrants special classification (Table 44.8). These data have resulted in the standard incorporation of aggressive techniques to prevent the occurrence of hypothermia in trauma patients, beginning with field transport with warm blankets and heated IV fluids and progressing to routine use of body and fluid rewarmers in emergency departments and operating rooms. Hypothermia is simply not acceptable in any trauma patient, and if it occurs, it should prompt a quality of care review.

Hypothermia appears to occur primarily in victims of relatively severe trauma. Little and Stoner, while reporting on a heterogeneous group of 82 trauma patients, observed that hypothermia occurred only in those patients with an ISS greater than 12. Hypothermia did not occur in less severely injured patients, and shivering, which should be expected, was noted in only one of the hypothermic patients. Mild degrees of injury have, in fact, been associated with small elevations in core body temperature, particularly when the shivering response mechanism has not been abated.[33] The recognition that hypothermia can be prevented has resulted in substantial changes in the management of the acutely injured patient. As a result, the "lethal triad" of coagulopathy, acidosis, and hypothermia is much less frequently observed.[34]

The detrimental effect of hypothermia in the human trauma victim is contrasted by a large body of experimental evidence in animals suggesting that hypothermia has a protective role in shock. This extensive body of literature is reviewed elsewhere, but in general, animals subjected to combined hypothermia and shock (hemorrhage, burn, and blunt trauma) usually survive longer than similarly injured but actively warmed animals. Blalock

TABLE 44.8 **Classification of Hypothermia**

CLASSIFICATION	CONVENTIONAL	TRAUMA PATIENT
Mild hypothermia	35°C–32°C (95.0°F–89.6°F)	36°C–34°C (96.8°F–93.2°F)
Moderate hypothermia	32°C–28°C (89.6°F–82.4°F)	34°C–32°C (93.2°F–89.6°F)
Severe hypothermia	28°C–20°C (82.4°F–68.0°F)	32°C (89.6°F)
Profound hypothermia	20°C–14°C (68.0°F–57.2°F)	

From Perlman R, Callum J, Laflamme C, et al. A recommended early goal-directed management guideline for the prevention of hypothermia-related transfusion, morbidity, and mortality in severely injured trauma patients. *Crit Care*. 2016 Apr 20;20(1):107.

and Mason (1941) were among the first in modern times to recognize the ability of hypothermia to prolong survival times after shock, but they emphasized that the overall survival rate was unchanged, an observation reaffirmed in 2003. However, increases in both survival times and survival rates have been shown in a number of animal models of induced hypothermia after hemorrhagic shock. The protective effects of hypothermia in preventing ischemia-reperfusion injury have been described in a number of models, including muscle, intestine, and rabbit ear.[35] These observations have prompted some to suggest that there is a role for iatrogenic-induced hypothermia in severe trauma patients, with the goal being a reduction of oxygen consumption in the setting of limited oxygen delivery (hypovolemic shock) to allow surgeons time to repair injured structures and then rewarm and resuscitate the patients.[36]

Hypothermia has also been used in attempts to protect the traumatically injured brain, but it is currently out of favor in most clinical settings. The use of therapeutic hypothermia in a patient with traumatic brain injury was first reported in 1943 and sporadically over the ensuing two decades. In 2001, Clifton et al. reported a randomized, multicenter, controlled trial of core body hypothermia in trauma patients with severe closed head injury. Select trauma patients (Glasgow Coma Scale [GCS] score of 3–7) were intentionally cooled within 6 hours of injury to 32°C to 33°C for 48 hours after injury and then rewarmed. The outcome was poor (defined as severe disability, a vegetative state, or death) in 57% of the patients in both groups. Mortality was 28% in the hypothermia group and 27% in the normothermia group ($p = 0.79$). The patients in the hypothermia group had more hospital days with complications than the patients in the normothermia group. This study and current-era multicenter studies like the 2018 Prophylactic Hypothermia Trial to Lessen Traumatic Brain Injury–Randomized Clinical Trial (POLAR-RCT) have led most authorities to conclude that treatment with total-body hypothermia is not effective in improving outcomes in patients with severe brain injury. Other authors have also reported higher rates of pneumonia and diabetes insipidus in patients with severe head injury and induced hypothermia.

Evidence further supporting the harmful effect of hypothermia in the trauma patient is provided by a prospective, randomized trial of rapid rewarming versus conventional rewarming of 57 multiple-trauma patients.[37] In this study, trauma patients who were rapidly rewarmed with continuous arteriovenous rewarming (CAVR) from less than 34.5°C to greater than 36°C required less resuscitation fluid volume and had a lower early mortality rate than those rewarmed more slowly. Failure to rewarm in either group was uniformly fatal. The survival rate at 3 days after injury was 82% in the rapid rewarm group versus 62% in conventionally managed patients. Approximately 50% of the patients in both groups had a severe head injury, defined as a head abbreviated ISS of 3 or greater. In this well-controlled study, maintenance of hypothermia not only failed to confer an advantage but also was detrimental to early survival.

The use of hypothermia in the treatment of acute cardiac arrest is beyond the scope of this chapter. However, as noted by the International Liaison Committee on Resuscitation (ILCOR) Advanced Life Support Task Force, among adult patients with cardiac arrest, the use of targeted temperature management at 32°C to 34°C, when compared with normothermia, does not result in improved outcomes whether initiated prehospital or in-hospital.[38] The ongoing attraction of hypothermia in patients with any cause of shock or hypoperfusion is the same as the principle of organ preservation for transplantation—cooling of the body decreases oxygen consumption and may allow for a longer period of relative anoxia with good recovery. The attraction for the concept of "suspended animation" with induced hypothermia in trauma remains seductive, and ongoing work is occurring (e.g., Emergency Preservation and Resuscitation for Cardiac Arrest from Trauma [EPR-CAT]).

The systems most affected by hypothermia in victims of injury are those involved in clotting. Focused attention on the coagulation mechanisms in trauma patients over the past decade has exposed the lack of a comprehensive understanding of the complex relationship between injury, inflammation, and coagulopathy. Temperature is yet another variable in this complexity. Reports of coagulation abnormalities in patients with apparently normal clotting factor levels surfaced shortly after the introduction of hypothermic cardioplegia for cardiac surgery. Although hemodilution with volume expanders deficient in clotting factors and platelets is a cause of nonsurgical bleeding, cold platelets are known to undergo morphologic changes that affect adherence, including loss of shape, cytoplasmic swelling, and dissolution of cytoplasmic microtubules necessary for normal motility. Platelet activation is also associated with activation of cell membrane phospholipases that hydrolyze phospholipids to arachidonic acid, a precursor to prostaglandin endoperoxides and thromboxane A_2, a potent vasoconstrictor necessary for normal platelet aggregation. Valeri et al. induced systemic hypothermia to 32°C in baboons but kept one forearm warm using heating lamps and a warming blanket. Simultaneous bleeding time measurements in the warm and cold arm were 2.4 and 5.8 minutes, respectively. This effect, which was reversible with rewarming, appeared to be mediated by cold-induced slowing of the enzymatic reaction rate of thromboxane synthetase, which resulted in decreased production of thromboxane A2. Bleeding observed at mildly reduced temperatures (33°C–37°C) results primarily from a platelet adhesion defect and not reduced enzyme activity or platelet activation; however, at temperatures below 33°C, both reduced platelet function and enzyme activity likely contribute to the coagulopathy, perhaps helping to explain why 32°C is such a critical temperature in the coagulopathic injured patient.

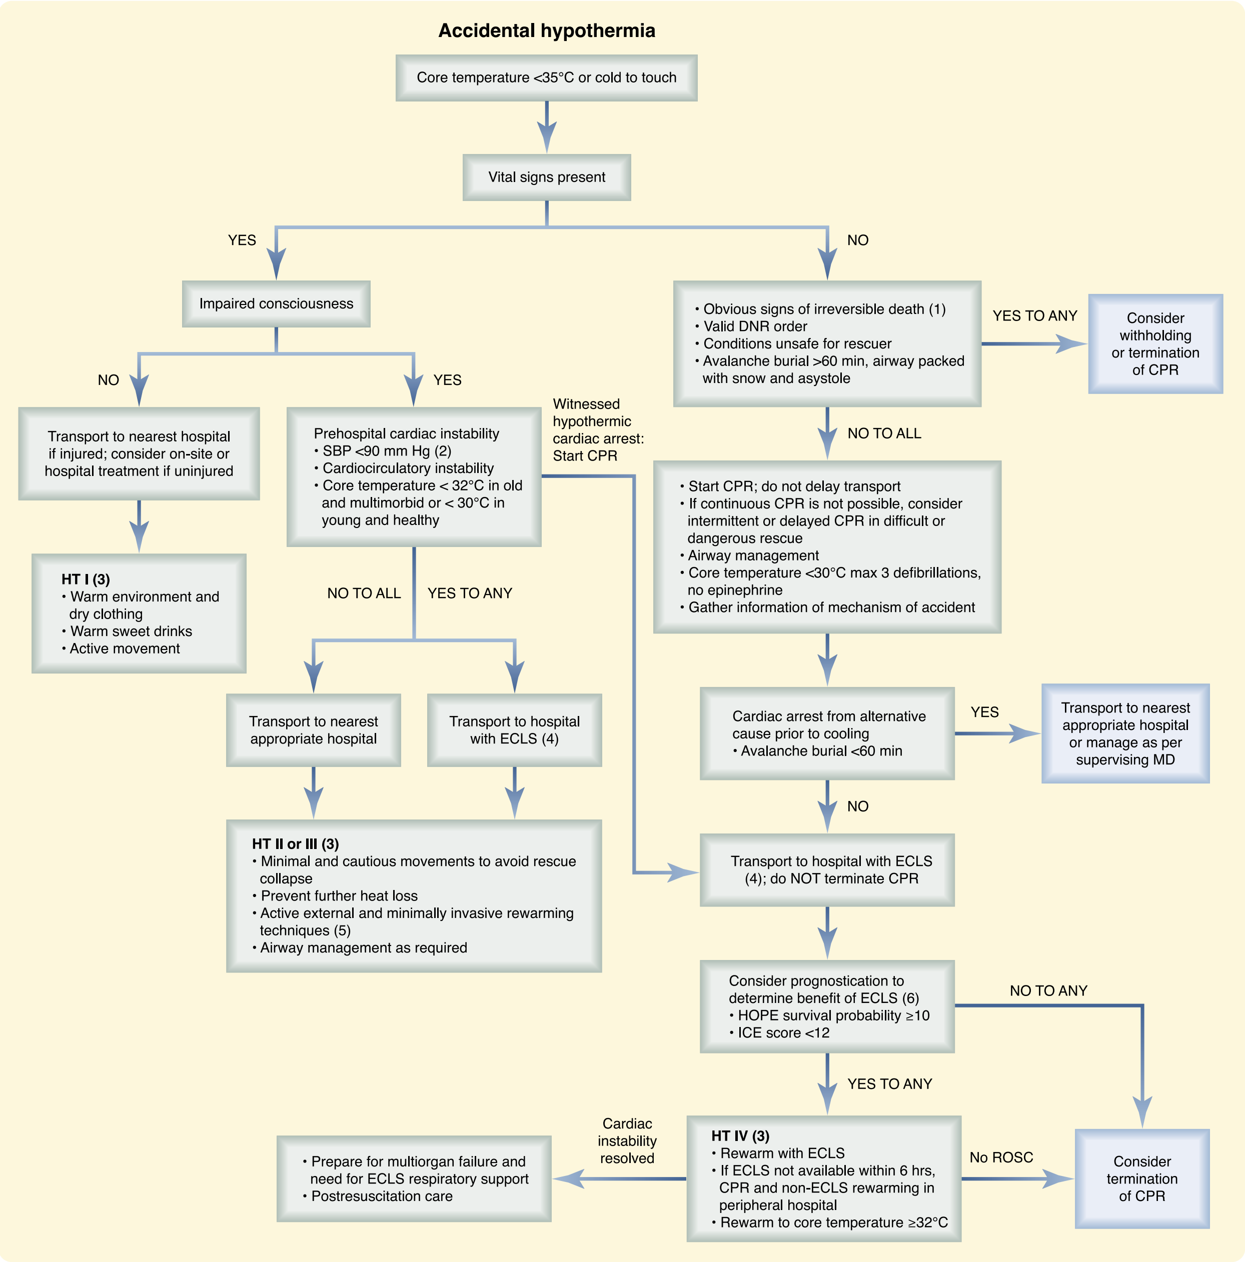
As with blood gases, clinical tests of coagulation are temperature standardized to 37°C. Fibrometers contain a thermal block that heats the plasma and reagents to 37°C before initiating the assay. Thus, tests of coagulation reflect clotting factor deficiencies but are corrected for any potential effect of hypothermia on clotting factor function. A detailed study of the kinetic effects of hypothermia on clotting factor function has been undertaken by Reed et al. He performed clotting tests (PT, PTT, and thrombin time) on reference human plasma containing normal clotting factor levels at temperatures ranging from 25°C to 37°C. The results showed a significant slowing of all coagulation tests at temperatures below 35°C that was proportional to the degree of hypothermia. The prolongation of clot formation occurred at clinically relevant levels of hypothermia and was equivalent to that seen in normothermic patients with significant clotting factor depletion. For example, assays conducted at 35°C, 33°C, and 31°C prolonged the PTT to the same extent as would occur in a euthermic patient with reductions in factor IX levels to 66%, 32%, and 7% of normal, respectively.

Clotting factor supplementation is not the answer to a hypothermia-induced coagulopathy; rewarming is. However, in many seriously injured patients, clotting factor depletion exists in conjunction with hypothermia. A potentiating effect of hypothermia on coagulation dysfunction occurs in plasma of patients with deficient clotting factor levels, although there does not appear to be synergy between the two conditions. Hypothermic, coagulopathic trauma patients still benefit from coagulation profile testing. If prolongation of PT and PTT is evident in plasma warmed to 37°C, clotting factor replacement is indicated. If PT and PTT are near normal, rewarming alone reverses the clinically apparent coagulopathy.

Treatment of Primary or Accidental Hypothermia

Treatment of accidental hypothermia remains highly variable. A study from Amsterdam reported that over an 8-year period (2000–08), a total of 84 patients with accidental hypothermia were treated with 14 different rewarming techniques, with an overall mortality of 28.6%. There are several excellent publications from European societies and authors on a step-wise, algorithmic approach to resuscitation of primary, accidental, or exposure hypothermic patients. Perhaps it is the long-standing history of mountaineering or the presence of emergency physicians in the field that is responsible. Fig. 44.21 is an example of this approach, based on the European Resuscitation Council, that has addressed the management of cardiac arrest in a number of special circumstances, including hypothermia. The key points to this treatment algorithm are the following:

- Check for the presence of vital signs for up to 1 minute to account for bradycardia and depressed ventilation.
- Accurate assessment of core temperature needs low-temperature thermometers.



Accidental hypothermia
Core temperature <35°C or cold to touch
Vital signs present
YES
NO
Impaired consciousness
NO
YES
Transport to nearest hospital if injured; consider on-site or hospital treatment if uninjured
HT I (3)
• Warm environment and dry clothing
• Warm sweet drinks
• Active movement
Prehospital cardiac instability
• SBP <90 mm Hg (2)
• Cardiocirculatory instability
• Core temperature < 32°C in old and multimorbid or < 30°C in young and healthy
Witnessed hypothermic cardiac arrest: Start CPR
NO TO ALL
YES TO ANY
Transport to nearest appropriate hospital
Transport to hospital with ECLS (4)
HT II or III (3)
• Minimal and cautious movements to avoid rescue collapse
• Prevent further heat loss
• Active external and minimally invasive rewarming techniques (5)
• Airway management as required
• Obvious signs of irreversible death (1)
• Valid DNR order
• Conditions unsafe for rescuer
• Avalanche burial >60 min, airway packed with snow and asystole
YES TO ANY
Consider withholding or termination of CPR
NO TO ALL
• Start CPR; do not delay transport
• If continuous CPR is not possible, consider intermittent or delayed CPR in difficult or dangerous rescue
• Airway management
• Core temperature <30°C max 3 defibrillations, no epinephrine
• Gather information of mechanism of accident
Cardiac arrest from alternative cause prior to cooling
• Avalanche burial <60 min
YES
Transport to nearest appropriate hospital or manage as per supervising MD
NO
Transport to hospital with ECLS (4); do NOT terminate CPR
Consider prognostication to determine benefit of ECLS (6)
• HOPE survival probability ≥10
• ICE score <12
NO TO ANY
YES TO ANY
HT IV (3)
• Rewarm with ECLS
• If ECLS not available within 6 hrs, CPR and non-ECLS rewarming in peripheral hospital
• Rewarm to core temperature ≥32°C
Cardiac instability resolved
• Prepare for multiorgan failure and need for ECLS respiratory support
• Postresuscitation care
No ROSC
Consider termination of CPR

FIGURE 44.21 Management of hypothermia from the European Resuscitation Council. *CPR,* Cardiopulmonary resuscitation; *DNR,* do not resuscitate; *ECLS,* extracorporeal life support; *HOPE,* Hypothermia Outcome Prediction After ECLS; *HT,* hypothermia; *ICE,* International Accidental Hypothermia ECLS; *MD,* doctor; *SBP,* systolic blood pressure.

- Prehospital insulation to prevent further heat loss.
- Initiate prompt transfer to a hospital with core rewarming capabilities and extracorporeal life support capabilities in severe cases.
- Prehospital cardiac instability is defined as a systolic blood pressure of <90 mm Hg or a core temperature <32°C in a patient with vital signs of life.
- Hypothermic cardiac arrest patients should receive continuous CPR during transfer. Chest compression and ventilation rate should not be different from CPR in normothermic patients.
- If ventricular fibrillation (VF) persists after three shocks, delay further attempts until the core temperature is >30°C.
- Withhold adrenaline if the core temperature is <30°C and increase administration intervals for adrenaline to 6 to 10 minutes if the core temperature is >30°C.
- If prolonged transport is required or the terrain is difficult, use of a mechanical CPR device is recommended.
- In hypothermic arrested patients with a core temperature of <28°C, delayed CPR may be used when on-site CPR is too dangerous or not feasible; intermittent CPR can be used when continuous CPR is not possible.

Rewarming techniques are usually classified as passive external rewarming, active external rewarming, or active core rewarming. Passive external rewarming simply implies allowing spontaneous rewarming to occur with the patient removed from a hypothermic environment and is usually used only for the mildly hypothermic patient. Active external rewarming techniques include surrounding the patient with warm blankets or heating pads, infrared heating lights, and immersion in warm water. Active core rewarming includes heated intravenous fluids, as well as heated peritoneal or thoracic lavage; heated gastric, bladder, or colonic lavage; heated and water-saturated inhaled air; and extracorporeal circulatory rewarming. Blood rewarming is currently limited to a maximum temperature of 42°C by the American Association of Blood Banks, but rewarming to 49°C with inline microwave blood rewarmers has been reported as safe, as has IV fluid rewarming to 65°C.

The advantages and disadvantages of each technique are regularly debated, particularly regarding the role of external versus core rewarming. It is clear, however, that the rate of heat transfer to the hypothermic patient is greatest using active core rewarming, particularly extracorporeal circulation rewarming. This may be a critical factor in surgical patients for whom rapid restoration of clotting and cardiac function is necessary.

The technique of rewarming the hypothermic victim by extracorporeal circulation has been described by numerous authors, initially based on small personal experiences and using CPB techniques of open-heart surgery. This technique has appeal in cases of primary accidental hypothermia, in which maintenance of circulation, correction of hypoxia, and replenishment of intravascular volume may play as large of a role as correcting the temperature change itself. The need for systemic anticoagulation has, however, generally limited the usefulness of full CPB rewarming in the trauma patient. More recently, the use of ECMO for core hypothermia rewarming has been the subject of numerous publications as more centers become more experienced with this tool.[39] A technique of extracorporeal active core rewarming that makes use of the patient's own blood pressure to drive an extracorporeal circuit through an efficient but small countercurrent heat-exchange device was developed, with demonstrated efficacy via improved survival,[37] but it is no longer in commercial production.

Direct intracirculation rewarming can be accomplished with commercially available devices that employ either a vena cava countercurrent heat-exchange device (InnerCool RTx, Phillips Healthcare, Best, the Netherlands; Thermogard XP Temperature Management System, Zoll Medical Corp., Chelmsford, MA) or balloon catheters with large surface areas (Alsius/Zoll Medical Irvine, CA). The ownership and design of these devices change rapidly because the clinical need is limited. Although initially developed to cool patients for neurosurgical procedures, they are now used primarily for inducing and maintaining hypothermia after sudden cardiac arrest; rewarming can be accomplished by simply changing the temperature of the closed-loop circulating fluid. Requirements are the commercial bedside console and the specialized endovascular temperature control catheter, inserted via the femoral vein to the vena cava, usually with a larger-size introducer (10–12 Fr). Data on rewarming cold patients suggest that rewarming can occur at up to 3°C per hour, compared with 6°C to 9°C per hour with ECMO or CPB.

The use of body cavity lavage with warm solutions is a simple, less invasive method of accomplishing active core rewarming; however, rewarming rates with body cavity lavage vary greatly based on initial core temperature, dialysate temperature, infusion rate, and dwell time. Several studies support the notion that active core rewarming by peritoneal lavage is preferable to active external rewarming. Moss examined three techniques of rewarming hypothermic and cardiac-arrested dogs, concluding that both peritoneal lavage (55°C dialysate) and partial extracorporeal circulation were faster than active external rewarming with a heating blanket. A frequently stated disadvantage of external rewarming is that the peripheral tissues are rewarmed in advance of the still cool "core," resulting in peripheral vasodilation leading to shock. In the presence of inadequate volume resuscitation, this rewarming method may result in vascular collapse ("rewarming shock") and a subsequent fall in central temperature ("afterdrop") as the cold peripheral blood returns to the core. Whether this process is the mechanism of the core afterdrop is debatable because continued cooling of a patient's core temperature during the initial states of rewarming has been noted to occur in animal models, even during complete circulatory arrest. Volume contraction caused by vasoconstriction, cold diuresis, and cellular swelling coupled with inadequate fluid resuscitation may be a more appropriate explanation for circulatory collapse during rewarming.

The thermodynamic principles of heat transfer to the hypothermic patient are reviewed in greater detail elsewhere,[40] but a sense of rewarming rates and quantity of heat transferred by various techniques is instructional. Ventilating a patient with a core temperature of 32°C with water-saturated air at 41°C results in a maximum heat transfer rate of 9 kcal/h. For comparison, basal metabolic heat generation produces approximately 70 kcal/h, and shivering produces up to 250 kcal/h. Given the specific heat of the body (0.083 kcal/kg/°C), 58 kcal is required to raise the temperature of a 70-kg patient by 1°C. Thus, more than 6 hours would be required to warm a 32°C patient using 41°C humidified inspired air.

Heat transfer rates using body cavity lavage can be similarly calculated based on the specific heat of water (1 kcal/kg/°C). If 1 L of 44°C water infused into a body cavity dwells long enough to exit at 40°C, 4 kcal of heat will have been transferred to the patient. Thus, over 14 L of fluid is needed to increase core temperature by 1°C. However, warming becomes less efficient as the patient rewarms because a longer dwell time is required to reduce the temperature of the infusate to 40°C.

Warming by CPB, ECMO, or CAVR is the most efficient method of core heating. With flow rates of 15 to 30 L/h, it is possible to deliver 120 to 240 kcal/h. If the reinfused blood is heated to 40°C, the rate of heat transfer is over 10 times that of the other methods. In any case, the urgency with which rewarming must be accomplished depends on how adversely the hypothermia is affecting the patient. Except for extracorporeal circulatory methods, most rewarming techniques serve primarily to prevent loss of endogenously generated heat and are ineffective in circumstances in which rapid rewarming is indicated. Early and direct attention to preventing heat loss is therefore essential in surgical patients. With more widespread adoption of ECMO capabilities for treating severe lung disease, centers are starting to report on the use of this modality as a rewarming technique. The combination of injury and hypothermia represents a particular challenge. Swiss physicians with experience in treating injured and hypothermic avalanche victims have developed the Bernese Hypothermia Algorithm, a detailed approach to rewarming techniques and injury care priorities in this population.

Cold Injury and Frostbite

Frostbite is a cold injury limited to digits, extremities, or exposed surfaces that is the result of direct tissue freezing. Chilblain (aka pernio) and trench foot are the result of more chronic exposure to an environment just above freezing. Both types of cold injury have been a major cause of morbidity during war experiences. They resulted in more than 7 million lost soldier fighting days by Allied forces in World War II and were reportedly the most common major injury sustained by British soldiers in the Falklands expedition. Upton Sinclair's novel *The Jungle* used the cold exposure of Chicago's meatpacking industry in the early 20th century to depict the pain of frostbite and chilblains and deplored the working conditions and exploitation of immigrants.

The terms *chilblain* and *pernio* describe a form of local cold injury characterized by pruritic, red-purple papules, macules, plaques, or nodules on the skin. Chilblains can result in a specific form of dermopathy secondary to cold-induced skin vasculitis. The lesions are often associated with edema or blistering and are caused by chronic vasculitis of the dermis; this entity does not appear to be related to hereditary protein C or S deficiency. This pathologic process is provoked by repeated exposure to cold, but not freezing, temperatures. This injury typically occurs on the face, the anterior surface of the tibia, or the dorsum of the hands and feet—areas poorly protected or chronically exposed to the environment. With continued exposure, ulcerative or hemorrhagic lesions may appear and progress to scarring, fibrosis, and atrophy. Treatment consists of sheltering the patient, elevating the affected part, and allowing gradual rewarming at room temperature. Rubbing and massage are contraindicated because they can cause further damage and secondary infection. Chronic treatment strategies are similar to frostbite injury treatment, with similar limited success (see later).

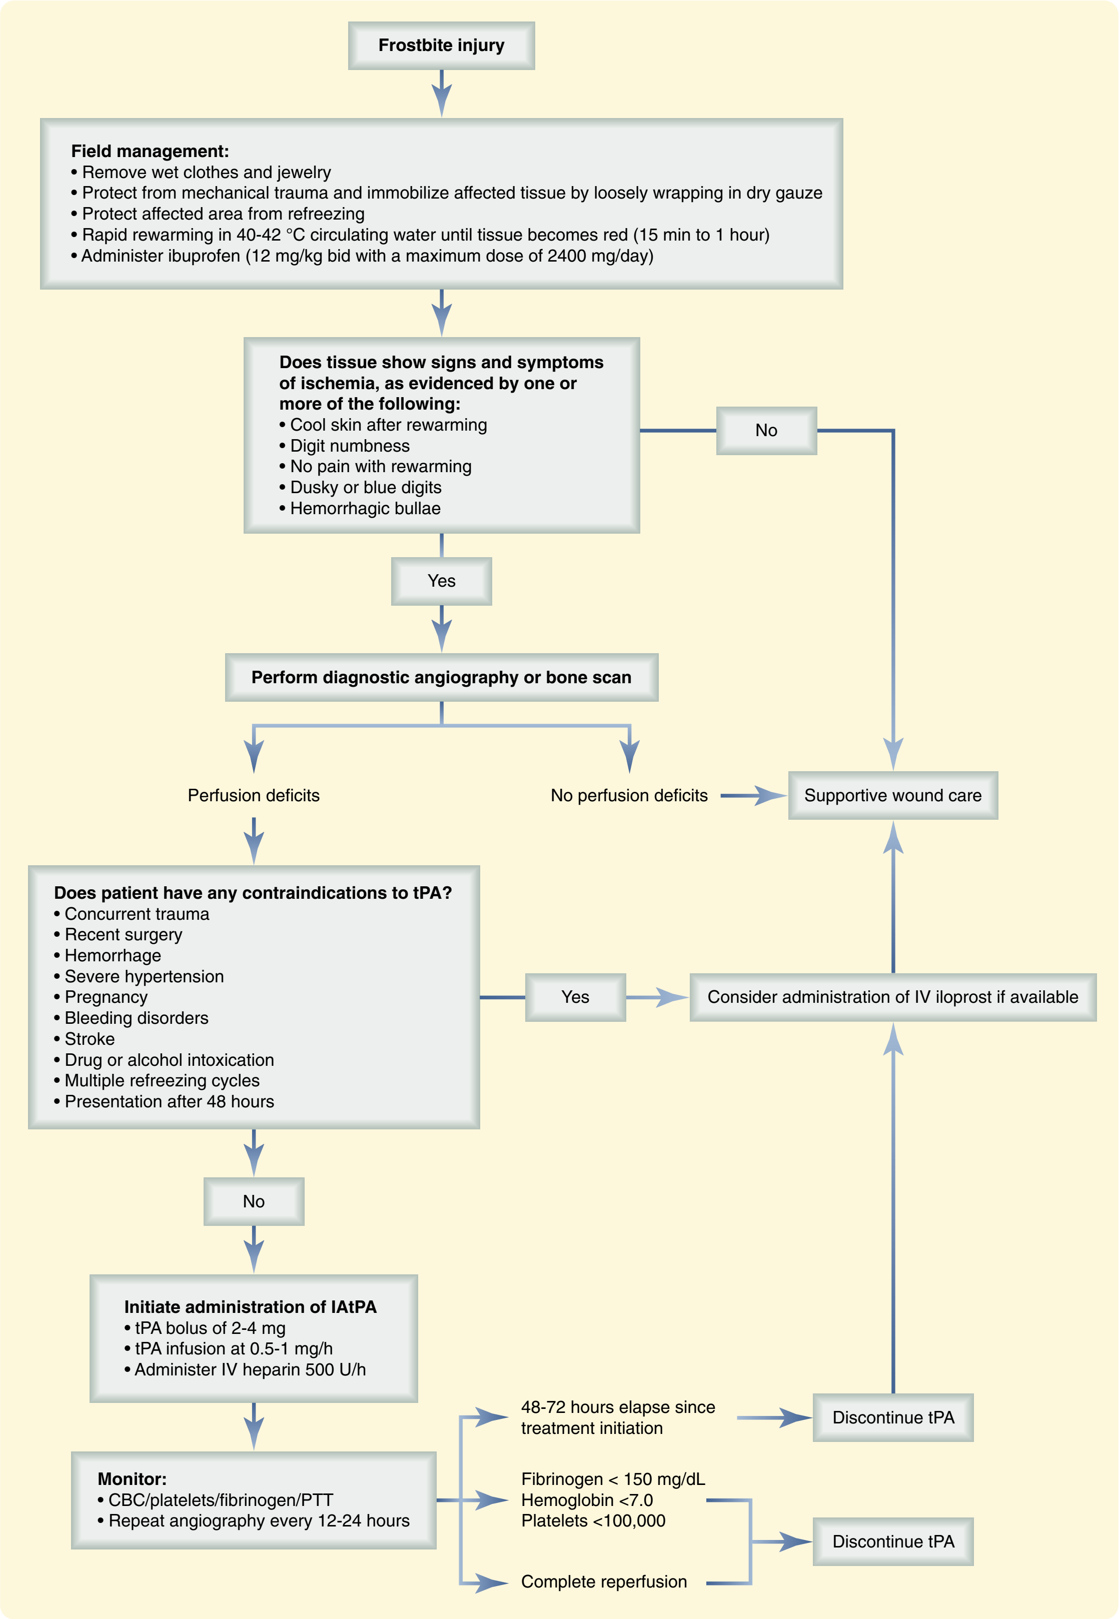
Trench foot or cold immersion foot (or hand) describes a nonfreezing injury of the hands or feet, typically in sailors, fishermen, or soldiers, that is caused by chronic exposure to wet conditions and temperatures just above freezing. It appears to involve alternating arterial vasospasm and vasodilatation, with the affected tissue first cold and anesthetic and then hyperemic after 24 to 48 hours of exposure. With the hyperemia comes an intense, painful burning and dysesthesia; tissue damage is characterized by edema, blistering, redness, ecchymosis, and ulceration. Complications of local infection or cellulitis, lymphangitis, and gangrene may occur. A posthyperemic phase occurs 2 to 6 weeks later and is characterized by tissue cyanosis with increased sensitivity to cold. Treatment is best started during or before the reactive hyperemia state and consists of immediate removal of the extremity from the cold, wet environment and exposure of the feet (or hands) to warm, dry air. Elevation to minimize edema, protection of pressure spots, and local and systemic measures to combat infection are indicated. Massage, soaking of the feet, or rapid rewarming is not indicated. Demyelination of nerves, muscle atrophy, fallen arches, and osteoporosis may all present long-term complications, and a tendency toward marked vasospasm during subsequent exposure to cold develops in some patients.

Frostnip is the mildest form of cold injury. It is characterized by initial pain and pallor, with subsequent numbness of the affected body part. Skiers and other winter outdoor enthusiasts are most likely to experience this cold injury to the nose, ears, or tips of digits. The injury is reversible, and warming of the cold tissue results in return of sensation and function with no tissue loss. Frostbite is a more severe and common form of cold injury that can result in debilitating, long-term, irreversible morbidity. Frostbite damage is caused by direct ice crystal formation at the cellular level, with cellular dehydration and microvascular occlusion. Indirect cellular injury, also referred to as *progressive dermal ischemia,* is a progressive microvascular insult. After thawing, microvascular thrombosis, endothelial damage, intravascular sludging, and reperfusion injury all occur, resulting in continued cell injury and death. Current treatment modalities have focused on minimizing the indirect cellular or reperfusion injury, as discussed later.

Frostbite is traditionally classified into four grades of injury severity (Table 44.9). The affected body part nearly always initially appears hard, cold, white, and anesthetic, regardless of the depth of injury. Because the appearance of the lesion changes frequently during the course of treatment and because the initial treatment regimen (Fig. 44.22) is applicable for all degrees of insult, some

TABLE 44.9 Four-Level Classification of Frostbite Injuries

FROSTBITE INJURIES OF THE EXTREMITIES	GRADE 1	GRADE 2	GRADE 3	GRADE 4
Extent of initial lesion at day 0 after rapid rewarming	Absence of initial lesion	Initial lesion on distal phalanx	Initial lesion on intermediary (and) proximal phalanx	Initial lesion on carpal or tarsal area
Bone scanning at day 2	Useless	Hypofixation of radiotracer uptake area	Absence of radiotracer uptake area on the digit	Absence of radiotracer uptake area on the carpal/tarsal
Blisters at day 2	Absence of blisters	Clear blisters	Hemorrhagic blisters on the digit	Hemorrhagic blisters over carpal/tarsal
Prognosis at day 2	No amputation	Tissue amputation	Bone amputation of digit	Bone amputation of the limb; ± systemic involvement; ± sepsis
	No sequelae	Fingernail sequelae	Functional sequelae	Functional sequelae



Frostbite injury
Field management:
• Remove wet clothes and jewelry
• Protect from mechanical trauma and immobilize affected tissue by loosely wrapping in dry gauze
• Protect affected area from refreezing
• Rapid rewarming in 40-42 °C circulating water until tissue becomes red (15 min to 1 hour)
• Administer ibuprofen (12 mg/kg bid with a maximum dose of 2400 mg/day)
Does tissue show signs and symptoms of ischemia, as evidenced by one or more of the following:
• Cool skin after rewarming
• Digit numbness
• No pain with rewarming
• Dusky or blue digits
• Hemorrhagic bullae
No
Yes
Perform diagnostic angiography or bone scan
Perfusion deficits
No perfusion deficits
Supportive wound care
Does patient have any contraindications to tPA?
• Concurrent trauma
• Recent surgery
• Hemorrhage
• Severe hypertension
• Pregnancy
• Bleeding disorders
• Stroke
• Drug or alcohol intoxication
• Multiple refreezing cycles
• Presentation after 48 hours
Yes
Consider administration of IV iloprost if available
No
Initiate administration of IAtPA
• tPA bolus of 2-4 mg
• tPA infusion at 0.5-1 mg/h
• Administer IV heparin 500 U/h
Monitor:
• CBC/platelets/fibrinogen/PTT
• Repeat angiography every 12-24 hours
48-72 hours elapse since treatment initiation
Discontinue tPA
Fibrinogen < 150 mg/dL
Hemoglobin <7.0
Platelets <100,000
Discontinue tPA
Complete reperfusion

FIGURE 44.22 Frostbite management algorithm. Key management of frostbite injury begins with proper field management and rapid rewarming. After rewarming, identification of tissue ischemia with diagnostic angiography or bone scans is often necessary. If tPA is administered, patients require monitoring of CBC/platelets/fibrinogen and PTT to avoid hemorrhagic events. *CBC,* Complete blood count; *PTT,* partial thromboplastin time; *IAtPA,* intraarterial tissue plasminogen activator; *tPA,* tissue plasminogen activator. (From Zaramo TZ, Green JK, Janis JE. Practical review of the current management of frostbite injuries. *Plast Reconstr Surg Glob Open.* 2022 Oct 24;10[10]:e4618.)

authorities suggest discarding this classification as a prognostic impossibility and simply classifying frostbite as either superficial or deep.[41]

Weather conditions, altitude, degree of protective clothing, duration of exposure, and degree of tissue wetness are all contributing external factors to the development of frostbite injury. Because sensory nerve activity is abolished at 7°C to 9°C, the disappearance of pain is an early warning sign of cold injury. Acclimation to cold may be protective, whereas a previous history of frostbite probably predisposes to another cold tissue injury. Smoking and a history of arterial disease also are contributing factors. In urban environments, more than 50% of frostbite injuries are alcohol related, and in one report, 16% of these patients also had a significant underlying psychiatric illness.

As noted, frostbite injury has two components: the initial freeze injury and a reperfusion injury that occurs during rewarming. The initial response to tissue cooling is vasoconstriction and arteriovenous shunting, intermittently relieved (every 5–7 minutes) by vasodilation, the so-called "hunting response." With prolonged exposure, this response fails, and the temperature of the freezing tissue approximates ambient temperature until –2°C. At this point, extracellular ice crystals form, and as these crystals enlarge, the osmotic pressure of the interstitium increases, resulting in movement of intracellular water out of cells and into the interstitium. Cells begin to shrink and become hyperosmolar, disrupting cellular enzyme function. If freezing is rapid ($>$10°C/min), intracellular ice crystal formation will occur, resulting in immediate cell death. In addition, endothelial cell disruption and red cell sludging associated with freezing result in cessation of circulation.

During rewarming, aggregation of red cells, platelets, and leukocytes occurs and results in patchy thrombosis of the microcirculation. These accumulated blood elements are thought to release, among other products, the toxic oxygen free radicals and the arachidonic acid metabolites PGF_{2a} and thromboxane A_2, which further aggravate vasoconstriction and platelet and leukocyte aggregation. However, the exact mechanism of tissue destruction and death after freeze injury remains poorly defined. Animal studies suggest that vascular injury in the form of endothelial cell damage and subsequent interstitial edema, but not vessel thrombosis, predominate as initial events in rewarming injury. A substantial component of severe cold injury may be neutrophil mediated, as suggested by the observation that a monoclonal antibody to neutrophil–endothelial and neutrophil–neutrophil adherence can markedly ameliorate the pathologic process of a severe cold injury.[42] In this rabbit model, animals treated with anti-CD11/CD18 adhesion molecule after cold injury (30 minutes at –15°C) but before rewarming (39°C water bath) had significantly less tissue loss and edema. The implication of these observations is that much of the injury of severe frostbite occurs during rewarming or reperfusion, although the efficacy of intraarterial thrombolytic therapy suggests that endovascular clotting does occur and can be reversed.

Treatment of Cold Injury

Prehospital or field care of the victim of cold injury should focus on removing the patient from the hostile environment and protecting the injured body part from further damage. Rubbing or exercising the affected tissue does not augment blood flow and risks further cold injury or mechanical trauma. Because repeated bouts of freezing and thawing worsen the injury, it is preferable for the patient with frostbite of the hands or feet to seek definitive shelter and care immediately rather than rewarming the tissue in the field and risking refreezing. Although the initial symptoms may be mild and overlooked by the patient, severe pain, burning, edema, and even necrosis and gangrene may appear with rewarming. With severe injury, the range of motion progressively decreases, and edema becomes prominent. The injury may progress to numbness and, eventually, to loss of all sensation in the affected tissue.

The emergency room treatment of a frostbite victim should first focus on the basic ABCs (airway, breathing, and circulation) of trauma resuscitation, and then systemic hypothermia should be identified and corrected. Most patients are dehydrated, and resuscitation with warm fluids is an important part of early management. Fractures are often accompanied by frostbite in mountaineers, and although manipulation may be required to treat vascular compromise, open reduction is hazardous, and application of traction should be delayed until after post-thawing edema has been assessed.

Rapid rewarming is the goal. Gradual, spontaneous rewarming is inadequate, particularly for deeper injuries, and rubbing the injured part in ice or snow often delays warming and results in marked tissue loss. Rapid rewarming should be achieved by immersing the tissue in a large water bath of 40°C to 42°C (104°F–108°F). The water should feel warm, but not hot, to the normal hand. The bath should be large enough to prevent rapid loss of heat, and the water temperature should be maintained. Dry heat is not advocated because it is difficult to regulate, and the result of using excessive heat is often disastrous. The rewarming process should take approximately 30 to 45 minutes for digits, with the affected area appearing flushed when rewarming is complete and good circulation has been reestablished. Narcotics can be required because the rewarming process can be quite painful.

The skin should be gently but meticulously cleansed and air-dried, and the affected area should be elevated to minimize edema. A tetanus toxoid booster should be administered as indicated by immunization history. Sterile cotton is placed between toes or fingers to prevent skin maceration, and extreme care is taken to prevent infection and avoid even the slightest abrasion. The affected tissue should be protected by a tent or cradle, and pressure spots must be prevented. In one review, infection developed in 13% of urban frostbite victims, but one-half of these infections were present at the time of admission. Most clinicians reserve antibiotics for identified infections.

After rewarming, the treatment goals are to prevent further injury while awaiting the demarcation of irreversible tissue destruction. All patients should be hospitalized, and affected tissue should be gently cleansed once or twice a day in warm (38°C) whirlpool baths, with some clinicians adding an antiseptic such as chlorhexidine or an iodophor to the bath. Based on the findings of arachidonic acid metabolites in the blisters of frostbite victims, some authors advocate the use of topical aloe vera (thromboxane inhibitor) and systemic ibuprofen or aspirin. Uninfected blebs should be left intact because they provide a sterile biologic dressing for 7 to 10 days and protect underlying epithelialization. After resolution of edema, digits should be exercised during the whirlpool bath and physical therapy begun. Tobacco, nicotine, and other vasoconstrictive agents must be withheld. Weight bearing is prohibited until complete resolution of edema.

The use of technetium-99m methylene diphosphonate bone scanning has shown some promise in the early detection of eventual bone and soft tissue viability, as has the use of magnetic resonance imaging and arteriogram. Technetium-99m "triple-phase" scanning (at 1 minute, 2 hours, and 7 hours) performed beginning 48 hours after admission has been used to assess early tissue perfusion and viability in an attempt to define the extent of fatally damaged tissues and allow for early debridement and wound closure. Current literature advises delayed surgery (~2–4 weeks after injury) with soft tissue debridement and bone scan–guided amputation (Fig. 44.23).[41]

Numerous adjuvants have been tried to restore blood supply to frostbitten areas. The intense vasoconstrictive effect of cold injury has focused attention on increased sympathetic tone. Sympathetic blockade and even surgical sympathectomy have been used by some based on the theory that they release the vasospasm that precipitates thrombosis in the affected tissue. These methods of treatment have produced inconsistent results and are difficult to evaluate clinically, with no prospective, randomized trials available. Although sympathectomy appears to mollify the pain, hyperhidrosis, and vasospasm of cold injuries, it may increase vascular shunting and adversely affect healing. In one series of patients with cold injuries in Alaska, a more proximal demarcation of injury in sympathectomized limbs was noted than in nonsympathectomized ones, despite apparently equal bilateral injury.

Experience with intraarterial vasodilatory reserpine, tolazoline, and papaverine has also been unrewarding. In a controlled clinical study, immediate (mean 3 hours) ipsilateral intraarterial reserpine infusion coupled with early (mean 3 days) ipsilateral operative sympathectomy failed to alter the natural history of acute frostbite injury compared with the contralateral limb. Low-molecular-weight dextran has been shown to alleviate post-thawing circulatory obstruction as late as 2 hours after thawing and markedly reduced tissue loss in rabbit feet, but similar results in humans have not been demonstrated. Heparin, thrombolytic agents, and hyperbaric oxygen have also failed to demonstrate any substantial treatment benefit, but hyperbaric enthusiasts continue to tout its role. None of these adjuncts is considered routine care.

Intraarterial infusion of tissue plasminogen activator (tPA) has shown to be of benefit. In a nonrandomized study of a small number (n = 7) of patients who received intraarterial tPA, the burn team at the University of Utah demonstrated that tPA infusion improved tissue perfusion and reduced amputations (10% vs. 41%) when administered within 24 hours of injury (6 of the 7 patients), as compared with 25 patients managed in a more traditional fashion. Since this 2007 report, isolated case reports have also suggested that this therapy is effective. During tPA administration, serial angiography should be performed to determine improvement in perfusion, and it should be discontinued if no improvement is noted after 48 to 72 hours. IV heparin should be coadministered with intraarterial infusion of tPA to prevent the propagation of thrombosis.[41]

In 2024 the FDA formally approved the use of iloprost (Aurlumyn) to treat frostbite.[43] The primary data source for this approval was a study from 2011. Iloprost is a synthetic analog of prostacyclin PG12. It works by binding with equal affinity to human prostacyclin (Prostanoid IP) and prostaglandin EP1 receptors and acts as a vasodilator, relaxing the muscles in artery walls. This IV agent is touted to increase blood flow, relieve high blood

pressure, and inhibit platelet aggregation. The effectiveness of iloprost was determined by an open-label, randomized controlled trial that involved 47 patients with a mean age of 33 years; 94% were males. Of those studied, 70% had frostbite involving the feet, 62% had frostbite involving the hands, and 32% had frostbite involving both feet and hands. Those assigned to the groups that received iloprost IV for 6 hours daily for up to 8 days were reported to have a significantly lower presence of bone scintigraphy anomaly (a marker that is expected to predict the risk of amputation) than those assigned to received buflomedil (Loftyl), a vasoactive drug that is usually used to treat claudication but is not FDA approved.

What is termed the "Helsinki frostbite protocol" involves the use of intraarterial fibrinolytics (tPA) and/or intravenous vasodilator iloprost. Candidates for this therapy should have minimal risk of bleeding from other injuries; have the tPA administered (intraarterial or intravenously) within 24 hours of frostbite, with no episodes of rewarming or refreezing between injury and treatment; and have clear evidence of full-thickness tissue involvement, as well as abnormal perfusion on either angiogram or pyrophosphate scanning. In one study, 20 patients with frostbite were diagnosed between 2013 and 2016.[44] Nine patients underwent fibrinolytic treatment with tPA and/or iloprost. The overall digital salvage rate was 74.8%. However, as of January 2020, the American Burn Association guidelines state that the data are insufficient to support routine treatment of all patients with frostbite with thrombolytics,[45] but they do promote that patients with cyanosis persisting proximal to the distal phalanx (grade 3 or 4 frostbite injury) and demonstrated loss of perfusion at or proximal to the middle phalanx immediately after rewarming can be treated with thrombolytic therapy in accordance with local hospital protocols. The guidelines also support the concept that time to treatment is an important quality metric in the treatment of frostbite. The work from Hennepin County Burn Center supports the notion that "time is tissue," similar to the treatment of ischemic stroke or myocardial infarction. Nice summaries of the body of work on the history and treatment of frostbite injuries and the paucity of data on effective treatment were recently compiled.[41,45]

The difficulty in determining the depth of tissue destruction in cold injury has led to a conservative approach to the care of frostbite injuries.[47] For digit frostbite, the Hennepin score may provide a useful way to track progress and compare experimental therapies. As a general rule, amputation and surgical debridement are delayed for 2 to 3 months unless infection with sepsis intervenes—hence the adage: "Frostbite in January, amputate in June." The natural history of a full-thickness frostbite injury is the gradual demarcation of the injured area with dry gangrene or mummification clearly delineating nonviable tissue. Often, the permanent tissue loss is much less than originally suspected. In an Alaskan series, only 10.5% of patients required amputation, usually involving only phalanges or portions of phalanges. The need for emergency surgery is unusual, but vigilance should be maintained during the rewarming phase for the development of a compartment syndrome requiring fasciotomy. Open amputations are indicated in patients with persistent infection and sepsis that are refractory to debridement and antibiotics. Mills convincingly demonstrated that of all the factors in the treatment of frostbite that may influence outcome, premature surgical intervention by any means, in any amount, was by far the greatest contributor to poor results.

Frostbitten tissues seldom recover completely. Some degree of cold insensitivity invariably remains. Hyperhidrosis (in up to 72% of patients), neuropathy, decreased nail and hair growth, and a persistent Raynaud phenomenon in the affected part are frequent sequelae to cold injury.[48] The affected tissue remains at risk for reinjury and should be carefully protected during any cold exposure. Treatment with antiadrenergic agents (prazosin hydrochloride, 1–2 mg/d) or calcium channel blockers (nifedipine, 30 to 60 mg/d) and careful protection from further exposure is often helpful. However, few therapies afford significant relief of the chronic symptoms after tissue freeze injury, although β- and α-adrenergic blocking agents, calcium channel blockers, topical and systemic steroids, and a host of home remedies have been tried with occasional individual success.

SUMMARY

Of the 3700 species of snakes worldwide, only 200 are significantly venomous, with approximately six deaths per year in the United States caused by snakebite. In contrast, there are over 150,000 species of Hymenoptera (a large order of insects, comprising the sawflies, wasps, bees, and ants) in the world that cause approximately 40 deaths per year, mostly because of severe anaphylactic reactions.

Snakebite morbidity depends on the type of snake and the degree of envenomation. Venoms consist of numerous polypeptides that can disrupt endothelial cells and blood flow, produce neuromuscular blockade, or generate a coagulopathy via procoagulants. Some snakes (particularly Elapids, as represented by the coral snakes in North America) also have direct neurotoxins and cardiotoxins. Snakebite produces immediate pain, edema, and erythema at the site. Spread of the swelling greater than 10 cm/h indicates severe envenomation. Initial incision and suction and the use of a proximal tourniquet are contraindicated. Use of purified ovine antivenin is effective for serious *Crotalidae* envenomation and has replaced equine antivenin, given its associated risk of serum sickness. Because of the presumed safety of the newer antivenom, overuse is more likely.

Spider bites produce toxicity by local tissue necrosis (brown recluse and hobo spiders) and painful muscle contractions (black widow spider). Death may be caused by stinging Hymenoptera, including bees (particularly aggressive Africanized bees), fire ants, and scorpions. The death is usually secondary to anaphylaxis, but occasionally, massive envenomation occurs—especially with Africanized honeybees. The estimated lethal dose is approximately 20 stings/kg in most mammals.

Hypothermia risk is high in the severely injured patient because of exposure, loss of normal protective metabolism (i.e., shivering), rapid massive infusion of cold fluids/blood, and open thoracic and abdominal cavities. The initial response to hypothermia is an intensive sympathetic type of reaction with tremulousness, profound vasoconstriction, a marked increase in oxygen consumption, and accelerated heart rate and minute ventilation. As core temperature falls to between 33°C and 30°C, this response is lost, and deeper core hypothermia rapidly develops. Hypothermia increases risk of mortality at every level of traumatic injury. There is no improvement in outcome when hypothermia is applied to a patient with severe traumatic brain injury; trauma patients who are rapidly rewarmed require less resuscitation volume and have improved survival.

Treating hypothermia begins by preventing further heat loss and allowing endogenous rewarming. Active rewarming has many adjuncts, including warm blankets, heating pads and lights, and immersion in warm water or internally by core rewarming. Internal core rewarming is more effective and includes heated intravenous fluids, heated body cavity lavage, heated moist inhaled air, extracorporeal circulatory rewarming (ECMO or CPB), and closed-circuit intravascular countercurrent heat-exchange devices. Frostbite involves ice crystal formation and unpredictable loss of tissue. Early definitive rewarming (avoiding refreezing) by submersion in 40°C to 42°C water is preferable, with subsequent meticulous care, awaiting demarcation, and avoidance of early debridement to optimize outcomes and tissue salvage. Early thrombolytic and/or prostaglandin vasodilator therapy might be beneficial in select frostbite patients.

New Horizons

From the oldest descriptions of wound healing back in 2200 BCE to the numerous therapeutic advances nowadays, wound care has remained one of the most challenging topics in the medical field. Although the understanding of mechanisms involved in wound repair has improved over time, specific details regarding healing, especially in the setting of chronic wounds, are still lacking.

TISSUE INJURY AND RESPONSE

Wound repair refers to all attempts to restore mechanical integrity, reinstate the barriers to fluid loss and infection, and reestablish normal blood and lymphatic flow patterns. Unlike regeneration, in which perfect restoration of preexisting tissue architecture is achieved, in wound repair, flawless reconstruction is sacrificed to prioritize return to function. Regeneration is achievable only during embryonic development, in lower organisms, or in certain tissues such as bone and liver.

The path toward wound repair is universally composed of three stages: inflammation, proliferation, and maturation, which includes remodeling. Acute wounds are those that complete all three healing phases promptly. Chronic wounds stall in the inflammatory phase and fail to progress.

WOUND-HEALING

Wounds present in different stages of the wound-healing phases. For instance, in a large wound such as a pressure sore, the eschar or fibrinous exudate reflects the inflammatory phase, the granulation tissue is part of the proliferative phase, and the contracting or advancing edge is part of the maturational phase. All three phases may occur simultaneously, and the phases may overlap with their processes (Fig. 45.1).

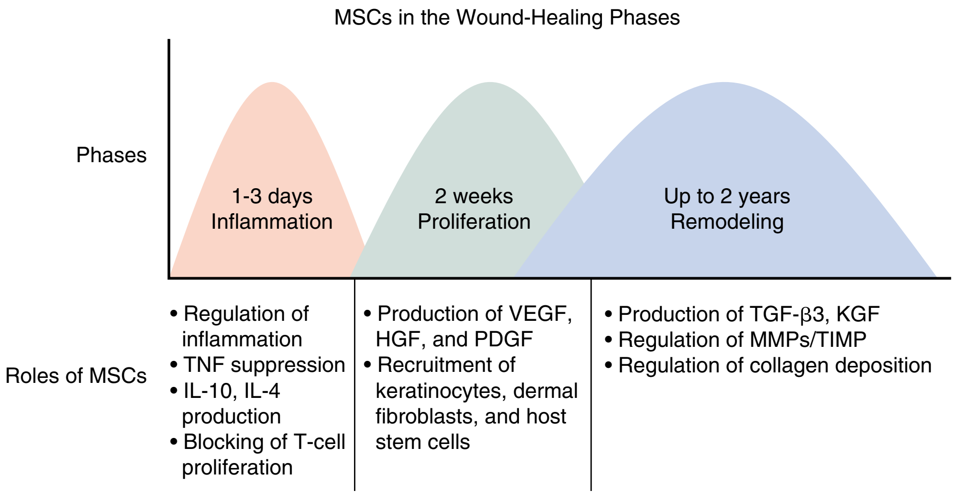
Phases

Inflammatory

During the immediate reaction of the tissue to injury, hemostasis occurs quickly and is rapidly followed by inflammation. This phase represents an attempt to limit damage by stopping bleeding; sealing the wound surface; and removing necrotic tissue, foreign debris, and bacteria. The inflammatory phase is characterized by increased vascular permeability, migration of cells into the wound by chemotaxis, secretion of cytokines and growth factors into the wound, and activation of the migrating cells (Fig. 45.2).

Proliferative

As the acute responses of hemostasis and inflammation begin to resolve, the scaffolding is laid for the repair of the wound through angiogenesis, fibroplasia, and epithelialization. This stage is characterized by the formation of granulation tissue, which consists of a capillary bed; fibroblasts; macrophages; and a loose arrangement of collagen, fibronectin, and hyaluronic acid. Numerous studies have used growth factors to modify granulation tissue, particularly fibroplasia. Adenoviral transfer, topical application, and subcutaneous injection of platelet-derived growth factor (PDGF), transforming growth factor-β (TGF-β), keratinocyte growth factor (KGF), vascular endothelial growth factor (VEGF), and epidermal growth factor (EGF) have been shown to increase the proliferation of granulation tissue.



MSCs in the Wound-Healing Phases
Phases
1-3 days
Inflammation
2 weeks
Proliferation
Up to 2 years
Remodeling
Roles of MSCs
• Regulation of inflammation
• TNF suppression
• IL-10, IL-4 production
• Blocking of T-cell proliferation
• Production of VEGF, HGF, and PDGF
• Recruitment of keratinocytes, dermal fibroblasts, and host stem cells
• Production of TGF-β3, KGF
• Regulation of MMPs/TIMP
• Regulation of collagen deposition

FIGURE 45.1 Mesenchymal stem cell *(MSC)* roles in each phase of the wound-healing process. *HGF,* Hepatocyte growth factor; *IL-4,* interleukin-4; *IL-10,* interleukin-10; *KGF,* keratinocyte growth factor; *MMPs,* matrix metalloproteinases; *PDGF,* platelet-derived growth factor; *TGF-β3,* transforming growth factor-β3; *TIMP,* tissue inhibitors of metalloproteinase; *TNF,* tumor necrosis factor; *VEGF,* vascular endothelial growth factor. (From Maxson S, Lopez EA, Yoo D, et al. Concise review: role of mesenchymal stem cells in wound repair. *Stem Cells Transl Med.* 2012;1:142-149.)

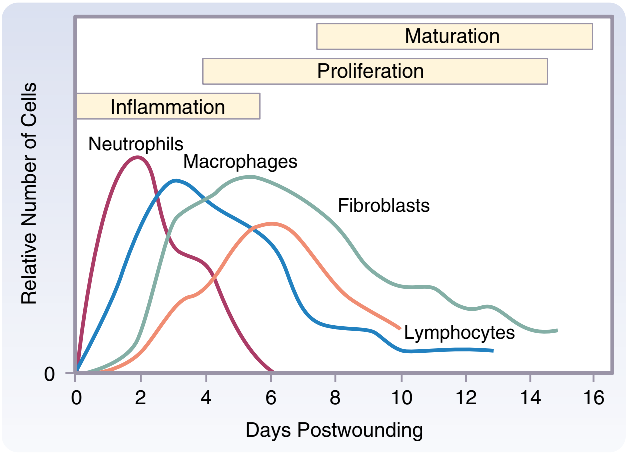


FIGURE 45.2 Time course of the appearance of different cells in the wound during healing. Macrophages and neutrophils are predominant during the inflammatory phase (peak at days 3 and 2, respectively). Lymphocytes appear later and peak at day 7. Fibroblasts are the predominant cells during the proliferative phase. (Adapted from Witte MB, Barbul A. General principles of wound healing. *Surg Clin North Am.* 1997;77:509-528.)

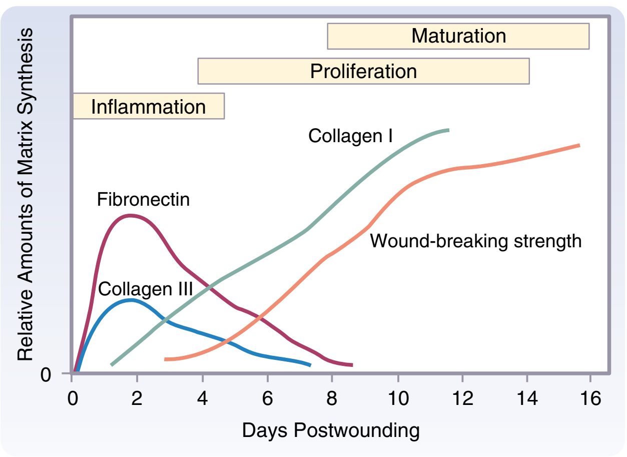

FIGURE 45.3 Wound matrix deposition over time. Fibronectin and type III collagen constitute the early matrix. Type I collagen accumulates later and corresponds to the increase in wound-breaking strength. (Adapted from Witte MB, Barbul A. General principles of wound healing. *Surg Clin North Am.* 1997;77:509-528.)

Maturational

Wound contraction occurs by centripetal movement of the whole thickness of the surrounding skin and reduces the amount of disorganized scar. Wound contraction appears to take place as a result of a complex interaction of the extracellular materials, which is addressed later, and fibroblasts that is not completely understood. Fibroblasts in a contracting wound change to stimulated cells, termed *myofibroblasts.* These cells have function and structure in common with fibroblasts and smooth muscle cells and express α-smooth muscle actin in bundles termed *stress fibers.* The actin appears on day 6 after wounding, persists at high levels for 15 days, and is gone by 4 weeks when the cell undergoes apoptosis. It appears that a stimulated fibroblast develops contractile ability related to the formation of cytoplasmic actin-myosin complexes. When this stimulated cell is placed in the fibroblast-populated collagen lattice, contraction occurs even more quickly. The tension that is exerted by the fibroblast's attempt at contraction appears to stimulate the actin-myosin structures in its cytoplasm. If colchicine, which inhibits microtubules, or cytochalasin D, which inhibits microfilaments, is added to the tissue culture, the result is minimal contraction of the collagen gels. Fibroblasts develop a linear arrangement in the line of tension that, when removed, causes the cells to round up.

Remodeling

The fibroblast population decreases, and the dense capillary network regresses. Wound strength increases rapidly within 1 to 6 weeks and then appears to plateau up to 1 year after the injury (Fig. 45.3). Compared with nonwounded skin, tensile strength is only 30% in the scar. An increase in breaking strength occurs after approximately 21 days, mostly as a result of cross-linking. Although collagen cross-linking causes further wound contraction and an increase in strength, it also results in a scar that is more brittle and less elastic than normal skin. In contrast to normal skin, the epidermal-dermal interface in a healed wound is devoid of rete pegs, the undulating projections of the epidermis that penetrate the papillary dermis. Loss of this anchorage results in increased fragility and predisposes the neoepidermis to avulsion after minor trauma.

Extracellular Matrix

The majority of the wound-healing stages take place or have direct interaction with the extracellular matrix (ECM). The ECM exists as a scaffold to stabilize the physical structure of tissues, but it also plays an active and complex role by regulating the behavior of cells that contact it. Cells within it produce the macromolecular constituents, including (1) glycosaminoglycans (GAGs), or polysaccharide chains, usually found covalently linked to protein in the form of proteoglycans, and (2) fibrous proteins such as collagen, elastin, fibronectin, and laminin.

- GAGs and proteoglycans: GAGs are unbranched polysaccharide chains composed of repeating disaccharide units, a sulfated amino sugar (N-acetylglucosamine or N-acetylgalactosamine), and uronic acid (glucuronic or iduronic). GAGs are highly negatively charged because of the sulfate or carboxyl groups on most of their sugars. Four types of GAGs exist: hyaluronan, chondroitin sulfate and dermatan sulfate, heparan sulfate, and keratan sulfate.

  GAGs in connective tissue usually constitute less than 10% of the weight of fibrous proteins. Their highly negative charge attracts osmotically active cations, such as Na^+, which causes large amounts of water to be incorporated into the matrix. This results in porous hydrated gels and is responsible for the turgor that enables the matrix to withstand compressive force.

  Proteoglycans are a diverse group of glycoproteins with functions mediated by their core proteins and GAG chains. The number and types of GAGs attached to the core protein can vary greatly, and the GAGs themselves can be modified by sulfonation. Because of their GAGs, proteoglycans provide hydrated space around and between cells. They also form gels of different pore sizes and charge densities to regulate the movement of cells and molecules.
- Collagen: Collagens are found in all multicellular animals and are secreted by various cell types. They are a major component of skin and bone and constitute 25% of the total protein mass in mammals. There are at least 20 types of collagen, the main constituents of connective tissue being types I, II, III, V, and XI. Type I is the principal collagen of skin and bone and is the most common. In adults, the skin is approximately 80% type I and 20% type III. In newborns, the content of type III collagen is greater than that found in adults. Other types of collagens include types IX and XII (fibril-associated collagens) and types IV and VII (network-forming collagens). Type IV molecules assemble into a meshlike pattern and are a major part of the mature basal lamina.

  Numerous factors can affect collagen synthesis. Vitamin C (ascorbic acid), TGF-β, insulin-like growth factor-1 (IGF)-1, and IGF-2 increase collagen synthesis. Interferon (IFN)-γ decreases type I procollagen messenger RNA (mRNA) synthesis, and glucocorticoids inhibit procollagen gene transcription, leading to decreased collagen synthesis.

  Several genetic disorders are caused by abnormalities in collagen fibril formation. In osteogenesis imperfecta, deletion of one procollagen α_1 allele results in weak, easily fractured bones. Ehlers-Danlos syndrome is a result of mutations affecting type III collagen and is characterized by fragile skin and blood vessels and hypermobile joints.
- Elastic fibers: Tissues such as skin, blood vessels, and lungs require strength and elasticity to function. Elastic fibers in the ECM of these tissues provide the resilience to allow recoil after transient stretching. Elastic fibers are predominantly composed of elastin, a highly hydrophobic protein (~750 amino acids long). Microfibrils appear before elastin in developing tissues and seem to form a scaffold on which the secreted elastin molecules are deposited. Elastin is produced early in life, stabilizes, and does not undergo much further synthesis or degradation, with a turnover that approaches the life span. Age-related modification is a result of progressive degradation as the elastic fibers gradually become tortuous, frayed, and porous.

  Mutations causing a deficiency of elastin protein result in arterial narrowing as a consequence of excessive smooth muscle cell proliferation in the arterial wall (intimal hyperplasia). These findings suggest that the normal elasticity of an artery is needed to prevent the proliferation of these cells. Gene mutations in fibrillin result in Marfan syndrome; severely affected individuals are prone to aortic rupture.
- Fibronectin: Soluble plasma fibronectin circulates in various body fluids and enhances blood clotting, wound healing, and phagocytosis. The highly insoluble fibrillar forms assemble on cell surfaces and are deposited in the ECM. The fibronectin fibrils that form on the surface of fibroblasts are usually coupled with neighboring intracellular actin stress fibers. The actin filaments promote the assembly of the fibronectin fibril and influence fibril orientation. Integrin transmembrane adhesion proteins mediate these interactions. The contractile actin and myosin cytoskeleton pull on the fibronectin matrix and generate tension.
- Laminin: Basal laminae are flexible, thin (40- to 120-nm) mats of specialized ECM that separate cells and epithelia from the underlying or surrounding connective tissue. The basal lamina acts in numerous ways: (1) as a molecular filter to prevent the passage of macromolecules (i.e., in the kidney glomerulus), (2) as a selective barrier to certain cells (i.e., the lamina beneath the epithelium prevents fibroblasts from contacting epithelial cells but does not stop macrophages or lymphocytes), (3) as a scaffold for regenerating cells to migrate, and (4) as an important element in tissue regeneration in locations where the basal lamina survives. Laminins generally consist of three long polypeptide chains (α, β, and γ). Mice lacking the laminin γ_1 chain die during embryogenesis because they cannot make a basal lamina.

In connective tissue, proteoglycan molecules form a gel-like ground substance. This highly hydrated gel allows the matrix to withstand compressive force while permitting rapid diffusion of nutrients, metabolites, and hormones between blood and tissue cells. Collagen fibers within the matrix serve to organize and strengthen the matrix, whereas elastin fibers give it resilience because matrix proteins have adhesive functions.

The wound matrix accumulates and changes in composition as healing progresses, balanced between new deposition and degradation (Fig. 45.4). The provisional matrix is a scaffold for cellular migration and is composed of fibrin, fibrinogen, fibronectin, and

FIGURE 45.4 Intracellular and extracellular events in the formation of a collagen fibril. (A) Collagen fibrils are shown assembling in the extracellular space contained within a large infolding in the plasma membrane. As one example of how collagen fibrils can form ordered arrays in the extracellular space, they are shown further assembling into large collagen fibers, which are visible with a light microscope. The covalent cross-links that stabilize the extracellular assemblies are not shown. (B) Electron micrograph of a negatively stained collagen fibril revealing its typical striated appearance. *ER,* Endoplasmic reticulum. vitronectin. GAGs and proteoglycans are synthesized next and support further matrix deposition and remodeling. Collagens, which are the predominant scar proteins, are the result. Attachment proteins, such as fibrin and fibronectin, provide linkage to the ECM through binding to cell surface integrin receptors.

Stimulation of fibroblasts by growth factors induces upregulated expression of integrin receptors, facilitating cell-matrix interactions. Ligand binding induces clustering of integrin into focal adhesion sites. Regulation of integrin-mediated cell signaling by the extracellular divalent cations Mg^{2+}, Mn^{2+}, and Ca^{2+} is perhaps caused by the induction of conformational changes in the integrins.

A dynamic and reciprocal relationship exists between fibroblasts and the ECM. Cytokine regulation of fibroblast responses is altered by variations in the composition of the ECM. For example, expression of matrix-degrading enzymes, such as the matrix metalloproteinases (MMPs), is upregulated after cytokine stimulation of fibroblasts. Collagenolytic MMP-1 is induced by interleukin-1 (IL-1) and downregulated by TGF-β. Activation of plasminogen to plasmin by plasminogen activator and procollagenase to collagenase by plasmin results in matrix degradation and facilitates cell migration. Modulation of these processes provides additional mechanisms whereby the cell-matrix interaction can be regulated during wound healing. Matrix modulation is also seen in tumor metastasis. Neoplastic cells lose their dependence on anchorage, mediated mainly by integrins; this is probably caused by decreased production of fibronectin and, subsequently, decreased adhesion, and as a result, these cells can break away from the primary tumor and metastasize.

An example of the necessary dynamic interactions occurring in the provisional matrix during wound healing is the effect of TGF-β on incisional wounds sealed with fibrin sealant. Fibrin sealant is a derivative of plasma components that mimics the last step in the coagulation cascade. Commercially available fibrin sealant has an approximately tenfold greater concentration of fibrin than plasma and consequently provides a more airtight, waterproof seal. Fibrin sealant may serve as a mechanical barrier to the early cell-mediated events occurring in wound healing. Supplementation of fibrin sealant with TGF-β has been demonstrated to reverse the inhibitory effects of fibrin sealant on wound healing and increase tensile strength compared with sutured wounds. The increased tensile strength may be a result of improved cell migration into the wound site, more rapid clearance of fibrin sealant, suppression of gelatinase (MMP-9), and enhancement of ECM synthesis in TGF-β–supplemented wounds.

Regulated turnover of the ECM is crucial to many biologic processes. ECM degradation occurs during metastasis when neoplastic cells migrate from their site of origin to distant organs via the bloodstream or lymphatics. In injury or infection, localized degradation of the ECM occurs so that cells can migrate across the basal lamina to reach the site of injury or infection. Locally secreted cellular proteases, such as MMPs or serine proteases, degrade the ECM components. Matrix proteolysis helps the cell migrate by (1) clearing a path through the matrix; (2) exposing binding sites, promoting cell binding or migration; (3) facilitating cell detachment so that a cell can move forward; and (4) releasing signal proteins that promote cell migration. Proteolysis is tightly regulated. Many proteases are secreted as inactive precursors that are activated when required. In addition, cell surface receptors bind these proteases to ensure that they act only on sites where they are needed. Finally, protease inhibitors, such as tissue inhibitors of metalloproteinase (TIMP), can bind these enzymes and block their activity.

ABNORMAL WOUND HEALING

Wound healing is a complex series of intertwining events that is affected by intrinsic and extrinsic factors (Box 45.1). The amount of tissue lost or damaged, the amount of foreign material or bacterial inoculation, and the length of exposure to toxic factors can affect the time to recovery. Intrinsic factors such as age, chronic medical conditions such as atherosclerosis, cardiac or renal failure, medications, genetic factors, and anatomic location of the wound all affect wound healing. Ultimately, the efficacy of the wound-healing process will be determined by the ability to go through the stages of wound repair promptly. When the regular repair mechanisms go amiss, one of two pathways develops: dysregulated and excessive formation of scar tissue termed *hypertrophic scarring* or *keloid* or a persistent and stagnant inflammatory state represented by an ulcerative skin defect designated *chronic wound*.

HYPERTROPHIC SCARS AND KELOIDS

Hypertrophic scars and keloids are proliferative scars characterized by dysregulated and excessive net collagen deposition from increased production or decreased degradation of collagen (Fig. 45.5). Hypertrophic scars are raised scars within the confines of the original wound that frequently regress spontaneously. Keloids, by definition, grow beyond the borders of the original wounds and rarely regress with time. The latter is more prevalent in darkly pigmented skin, developing in 15% to 20% of African Americans, Asians, and Hispanics. Keloids are more likely to be present in females. There is strong evidence suggesting a genetic susceptibility, including familial heritability, common occurrence in twins, and high prevalence in certain ethnic populations. Inheritance patterns can be autosomal dominant, autosomal recessive, or even X-linked. Single-nucleotide polymorphisms, as seen in Mendelian disorders, have been associated with keloids. Proposed pathways include apoptosis, endocytosis, cytokine-cytokine receptor interaction, mitogen-activated protein kinase signaling pathway, tenascin C, jun proto-oncogene, and growth factors such as TGF-β and VEGF.[1–4]

Infection

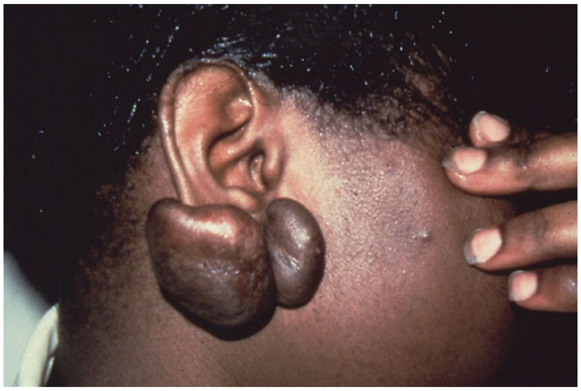

FIGURE 45.5 Keloids caused by ear piercing.

Keloids often occur above the clavicles, on the trunk, on the upper extremities, and on the face and less frequently on the palms, soles, and genitalia. Their occurrence cannot be predicted, and it can take place spontaneously or throughout an extended time period. This type of lesion can be hyperpigmented and associated with life-limiting pruritus, which is explained by a high quantity of mast cells in the keloid's dermal layer. Keloids are frequently refractory to medical and surgical intervention. To date, there is no known effective prevention method for keloid formation.

Keloids and hypertrophic scars differ histologically from normal scars. Hypertrophic scars primarily contain well-organized type III collagen, whereas keloids contain disorganized type I and type III collagen bundles (Table 45.1). Keloids and hypertrophic scars have stretched collagen bundles aligned in the same plane as the epidermis, whereas collagen bundles are randomly arrayed and relaxed in normal scars. Keloid scars have thicker, abundant collagen bundles that form acellular nodelike structures in the deep dermis with a paucity of cells centrally. Additionally, they contain higher levels of macrophages with increased affinity for the Th2-immune chronic response pathway, which enables them to secrete transforming growth factors constantly and promote collagen deposition.[3] Hypertrophic scars, in contrast, contain islands composed of aggregates of fibroblasts, small vessels, and collagen fibers throughout the dermis.

Hypertrophic scars are often preventable. High tension, prolonged inflammation, and insufficient resurfacing (e.g., burn wounds) promote hypertrophic scarring. Scars perpendicular to the underlying muscle fibers tend to be flatter and narrower, with less collagen formation than when they are parallel to the underlying muscle fibers. Tension appears to signal the formation of activated fibroblasts, resulting in excessive collagen deposition and thus a higher risk for dysregulated collagen accumulation. The position of an elective scar can be chosen to induce a narrower, less obvious healed scar. As muscle fibers contract, the wound edges become reapproximated when they are perpendicular to the underlying muscle and tend to gape if placed parallel to it, leading to greater wound tension and scar formation.

Hypertrophic scars represent a reversible hyperproliferative scar phenotype that tends to regress when the original stimuli (skin tension, stimulatory growth factors) are removed. Keloids appear to be genetically predisposed and are switched on irreversibly by growth factors. In addition, in these scars, collagen synthesis is elevated, whereas collagen degradation is low. MMPs are also affected in these scars: MMP-1 (collagenase) and MMP-9 (gelatinase, early tissue repair) are decreased, whereas MMP-2 (gelatinase, late tissue remodeling) is significantly elevated. Blocking TGF-β activity with antibodies decreases scar fibrosis. The use of mesenchymal stem cell (MSC) therapy to regulate the inflammatory pathway of hypertrophic scarring and keloids is currently being studied in rats. Systemic and topical injected MSCs have been noted to improve the macroscopical and histologic characteristics of these lesions.

Prevention of Hypertrophic Scars and Keloids

Some of the strategies that reduce adverse scarring immediately after wound closure are tension relief, pressure therapy, hydration/

TABLE 45.1 **Characteristics of Hypertrophic Scars and Keloids**

	HYPERTROPHIC SCARRING	KELOIDS
Description	Contained within the site of injury	Spread beyond the borders of the injury
Localization	Areas prone to high tension: back, chest, shoulders, elbows and other joints	Earlobes, shoulders, chest, back, cheeks, and knees
Collagen distribution	Wavy, regular pattern of type III collagen	Disorganized pattern, no distinct organization of type I and III collagen
Prognosis	Tend to regress over time and resolve completely	Persist
Response to excision	Low incidence of recurrence	High recurrence rate

occlusion, and the use of taping. Wounds with greater tension (perpendicular to Langer lines) or with excessive tension on closure and in certain anatomic locations (deltoid and sternal) are at a higher risk of adverse scarring. It is believed that greater tension results in a stronger activation of the inflammatory mechanisms, resulting in excessive scarring. Pressure therapy is used as an adjacent instrument to decrease the cytokine response and reduce collagen synthesis in scar formation, particularly in wide wounds. Pressure is applied via garments, bandages, adhesives, or specialized devices as soon as the patient can tolerate them. In general, wounds that remain hydrated tend to have less generation of static and mast cells. After wound healing, water still evaporates more rapidly through scar tissue and may take more than a year to recover to preinjury levels. Moisturizing lotions and moisture-retentive dressings can reduce the thickness, discomfort, and itching and improve the appearance of the scar. Sunscreen is a topical option that promotes hydration and protects the wound from ultraviolet light, which is known to increase pigmentation. Silicone products may ameliorate evaporative losses and assist in hydration of the stratum corneum. Silicon tape provides structural passive stabilization of the wound and decreases tension at the edges. These strategies need to be employed soon after initial wound healing.

Types of Treatments

Treatments can be divided into noninvasive, injectable, and surgical interventions. Noninvasive therapies include first-line silicone sheeting and pressure garments, as described earlier. For instance, early linear scar hypertrophy (e.g., after trauma or surgery) at 6 weeks to 3 months should be treated with pressure therapy. After 6 months, silicone therapy should be continued for as long as necessary if there is further scar maturation. Severe burns, mechanical trauma, necrotizing infections, wounds requiring more than 2 to 3 weeks to heal, or wounds healed with skin grafting require early application of silicone and compression therapy. This therapy should be initiated as soon as the wound is closed and the patient can tolerate the pressure. The mechanism of action of pressure therapy is poorly understood but may involve reduction of wound oxygen tension by occlusion of small blood vessels, resulting in a decrease in myofibroblast proliferation and collagen synthesis. Pressure therapy is believed to act on cellular mechanoreceptors that are involved in cellular apoptosis and linked to the ECM. The increased pressure regulates the apoptosis of dermal fibroblasts and diminishes hypertrophic scarring. Pressure and silicone therapy should be continued or intensified and combined with selective injections in resistant areas. Similarly, for keloids, first-line treatments include a combination of silicone dressings, pressure therapy, and injected steroids. Other noninvasive therapies include experimental medications on the market. Imiquimod, for example, has been targeted as an immune system–modulating agent when used topically as a cream, and the calcium channel blocker verapamil has been investigated for its role in collagen degradation. Data regarding the use of these medications are conflicting; thus, further research is required before considering them a first-line safe and standard-of-care option.

In the injectable category, intralesional corticosteroids are the first-line treatment for hypertrophic scarring and keloids. Their antiinflammatory and antiproliferative properties decrease collagen synthesis and fibroblast action. Ongoing hypertrophy unresponsive to noninvasive methods may be treated with intralesional corticosteroids (triamcinolone acetonide, 10–40 mg/mL) injected into the papillary dermis every 2 to 4 weeks until flat. This is the only noninvasive management option that has enough supporting evidence to be recommended in evidence-based guidelines. Approximately 50% to 100% of patients respond, and up to 50% experience recurrence. Adverse steroid effects include skin atrophy, hypopigmentation, telangiectasias, and excessive pain during injections. Injections should be limited to the scar itself to minimize adjacent fat atrophy. Although systemic effects are rare, certain cases with multiple lesions warranting concomitant injections can result in adverse consequences. Bleomycin, 5-fluorouracil (5-FU), and verapamil have been used as adjuncts to corticosteroid therapy. The pyrimidine analogue 5-FU is known to alter the cell cycle, promoting fibroblast apoptosis when used intralesionally, whereas bleomycin has proapoptotic and antiproliferative properties. Both 5-FU and bleomycin are novel therapies that require high-power clinical studies.

Surgical interventions include cryotherapy, excision, and laser. Cryotherapy is effective for small lesions. It can be applied intralesionally or topically via spray. In general, it has proven to be a suitable option, with a regression rate of up to 75% in the second session. Adverse events include depigmentation, pain, telangiectasia, skin atrophy, and recurrence. Regarding hypertrophic scarring, surgical scar revision may be considered for permanent linear hypertrophic scars present after 1 year. Simple resection and primary closure may be combined with adjacent tissue undermining, subcutaneous sutures, adjunctive Z-plasty, and postsurgical taping and silicone therapy. Hypertrophic scars can also be seen in conjunction with a scar contracture. Scar contractures involve abnormal shortening of unmatured scars, resulting in functional impairment, particularly if the scar is across a joint. Correction of a scar contracture generally requires surgery with Z-plasty, skin graft, or flap to release tension in the scar to restore function and reduce scar hypertrophy. Early surgery is indicated for functional impairment. Burn scar contracture release procedures in the neck and axilla are best performed with flaps to improve functional and cosmetic outcomes further, which may not be achievable with skin grafts. Widespread large hypertrophic scars may require serial excision or tissue expansion. Surgical excision for keloids is a controversial therapy. Excision alone results in a high recurrence rate of 50% to 100% and potential enlargement of the keloid. However, immediate postoperative electron beam irradiation or brachytherapy reduces recurrence rates by 50% to 95%. Ogawa and associates recently published a protocol of electron beam radiation for postsurgical excision based on high-risk areas for keloid recurrence.[5] Doses of 15 Gy for 2 days were applied to high-risk regions, such as those above the chest, and doses of 8 Gy for 1 day were applied to earlobes.[5] As a result, exposure to radiation decreased, and the rate of keloid recurrence was $<10\%$.[5] Finally, laser therapy is reserved for last after the first-line treatments fail. Commonly used machines include pulsed dye lasers, fractional CO_2 lasers, and laser Erbium-Yag (ER: YAG) resurfacing. Although this method reduces erythema, decreases the height of the keloid, and increases the pliability of the skin, further clinical trials are warranted.

Novel Therapies

New treatments for hypertrophic scarring and keloids include IFN, botulinum toxin, bleomycin, mitomycin, calcium channel blockers, MSC therapy, angiotensin-converting enzyme inhibitors, and fat grafting.

IFN—especially IFN-α and IFN-γ— has been shown to result in keloid size regression and decreased recurrence. The effect is secondary to the antiproliferative properties of these components. Although a decrease in collagen and an increase in collagenase have been seen, the rate of recurrence still remains above 50%. Thus, this therapy is better suited as an adjuvant treatment.

Regarding botulinum toxin, injecting it in the periphery of the wound will limit underlying muscle mobility and tension. This is thought to decrease the stimulus for collagen deposition, modulate fibroblastic activity, and alleviate tension at the wound site.[6] A recent literature review of intralesional botulinum toxin therapy in keloid scar management by Sohrabi and colleagues reported a reduction in keloidal volume, height, and vascularity, with outcomes comparable to those of intralesional corticosteroids.[6]

Angiotensin-converting enzyme inhibitors aid in scarring by modulating collagen production via the renin-angiotensin system because higher concentrations of angiotensin I receptors are seen in keloids. Both Captopril and Enalapril have been studied. Better outcomes are seen in recent scars rather than long-standing ones.

Mitomycin inhibits nucleic acid and protein synthesis. In humans, it decreases scar formation by inhibiting fibroblast proliferation. Mitomycin has had conflicting findings in the field of wound healing. In murine models, it has been shown to decrease the rate of scar contraction, whereas in rat models, it did not show long-term differences in wound characteristics after topical application.[7] Although mitomycin could potentially be considered as a treatment agent, further research is required.

Bleomycin inhibits the synthesis of DNA and the cross-linking of collagen fibers through the lysyl-oxidase enzyme. It is used in conjunction with injected corticosteroids (starting dose of 0.1 mL) after failure of monotherapy with the latter. When used weekly for a month by Huu and associates in a 55-patient study, 70.8% of scars had complete resolution, and the remaining had partial improvement.[4] Despite the promising results, the rate of recurrence was elevated, and side effects such as blisters, ulceration, and hyperpigmentation were reported.[4]

Calcium channel blockers, in particular verapamil, promote collagen degradation and induce fibroblast apoptosis, which results in decreased ECM component production. Intralesional verapamil use in conjunction with other therapies has been used in different plastic surgery procedures to improve and prevent abnormal scarring. Zhang and colleagues evaluated 9 randomized controlled trials involving 567 patients who underwent verapamil or triamcinolone intralesional injection for keloids and hypertrophic scars.[1] Although triamcinolone had superior results regarding reduction in height, pliability, and vascularity, verapamil had comparable long-term outcomes with a lower incidence of skin atrophy, telangiectasia, and hyperpigmentation.[1]

Stem cell therapy, especially MSCs, are known to release growth factors that hinder inflammatory response and promote antifibrotic components. Local and systemic injections of MSCs have been attempted in animal models. Bojanic and associates reviewed 11 case-control animal studies using MSCs for hypertrophic scarring ($n = 10$) and keloids ($n = 1$).[3] Improvement in the histologic and macroscopic appearance of the treated scars was noticed.[3] Despite the positive outcomes in animal models, there are no human studies currently available to evaluate the applicability of this treatment.

The idea behind fat grafting lies in the potential role of adipose-derived stem cells in regulating angiogenic growth factors and antiapoptotic proteins to decrease fibrous tissue and disorganized collagen deposition. Although there is a potential role for this therapy in scar treatment, research is extremely limited with this technique, even from the standpoint of adjuvant therapy.

Although existing strategies for the management of hypertrophic scars and keloids are broadly similar, the histologic differences between the two scars suggest that in the future, therapeutic approaches could be developed that are specifically tailored for these different types of scars. However, at present, there is no single proven best therapy for the management of these excessive healing scars, and the large number of treatment options reflects this (Table 45.2).

CHRONIC NONHEALING WOUNDS

By definition, chronic wounds are wounds that have failed to proceed through an orderly and timely reparative process to produce anatomic and functional integrity over a period of 3 months. The overall prevalence of chronic wounds worldwide is estimated to be 2.2 per 1000 population; the prevalence specifically for chronic leg ulcers is 1.51 per 1000 population.[8] In the United States, 1.6 million people are affected by diabetic foot ulcers (DFUs) per year,[9] up to 2 million patients per year develop chronic leg ulcers secondary to venous insufficiency, and 2 to 3 million patients per year develop pressure ulcers secondary to immobility. These numbers have been increasing as a result of an aging population and the rising incidence of risk factors for atherosclerotic disease, such as diabetes mellitus, cardiovascular disease, and smoking. These wounds are a significant challenge to healthcare professionals and an immense burden on healthcare systems and the economy. Patients also report reduced quality of life, psychological repercussions, and social isolation.

Different factors that promote adverse wound-healing conditions have been identified (Fig. 45.6). Systemic conditions, such as malnutrition, aging, tissue hypoxia, and diabetes, contribute significantly to the pathogenesis of chronic wounds. A combination of systemic and localized adverse wound factors collectively overwhelm the normal healing processes, resulting in a hostile wound-healing environment (Fig. 45.7).

Chronic wounds have derangements in the various stages of wound healing and have unusually elevated or depressed levels of cytokines, growth factors, or proteinases. Chronic wound fluid, in contrast to acute wound fluid, has been shown to have greater levels of IL-1, IL-6, and tumor necrosis factor-α (TNF-α); levels of these proinflammatory cytokines decreased as the wound

TABLE 45.2 Prevention and Treatment Options for Keloids and Hypertrophic Scars

MODALITY OR TREATMENT OPTION	RESPONSE RATE (%)	RECURRENCE RATE (%)	COMMENTS	STUDY DESIGN
Prevention				
Preventive silicone sheeting (postsurgery)	0–75	25–36	Multiple preparations available, tolerated by children, expensive, avoid on open wounds, poor study design	Review of multiple case studies
Postsurgical intralesional corticosteroid injection (triamcinolone acetonide [Kenalog], 10–40 mg/mL at 6-week intervals)	NA	0–100 (mean, 50)	Patient acceptance and safety; may cause hypopigmentation, skin atrophy, telangiectasia	Review of multiple case studies
Postsurgical topical imiquimod, 5% cream (Aldara)	NA	28	May cause hyperpigmentation, irritation	Case study
Postsurgical fluorouracil, triamcinolone acetonide, and pulsed dye lasers (best outcomes)	70 at 12 weeks	NA	Effective; may cause hyperpigmentation, wound ulceration	Clinical trial
First-Line Treatment				
Postsurgical radiation therapy	80–100	<10	Local growth inhibition	Clinical trials
Intralesional corticosteroid injection (triamcinolone acetonide [Kenalog], 10–40 mg/mL at 6-week intervals)	50–100	9–50	Inexpensive, requires multiple injections; may cause discomfort, skin atrophy, telangiectasia	Review of multiple case studies
Silicone elastomer sheeting	50–100	NA	Multiple preparations available, tolerated by children, expensive, poor study design	Review of multiple case studies
Pressure dressing (24–30 mm Hg) worn for 6–12 months	90–100	NA	Inexpensive, difficult schedule, poor adherence	Review of multiple case studies
Cryotherapy	50–76	NA	Useful on small lesions; easy to perform; may cause hypopigmentation, pain	Review of multiple case studies
Surgical excision alone	NA	50–100	Z-plasty option for burns; immediate postsurgical treatment needed to prevent regrowth	Review of multiple case studies
Combined cryotherapy and intralesional corticosteroid injection	84	NA	See benefits of individual treatments; may cause hypopigmentation	Case study
Triple-keloid therapy (surgery, corticosteroids, silicone sheeting)	88 at 13 months	12.5 at 13 months	Tedious, time intensive, expensive	Case study
Pulsed dye laser	NA	NA	Specialist referral needed, expensive, variable results depending on trial (controversial)	Case studies
Second-Line and Alternative Treatment				
Verapamil, 2.5 mg/mL, intralesional injection combined with perilesional excision and silicone sheeting	54 at 18 months	NA	Repeated injections, limited experience, may cause discomfort	Clinical trial
Fluorouracil, 50 mg/mL, intralesional injection two to three times a week	88	0	Effective; may cause hyperpigmentation, wound ulceration	Review of multiple case studies
Bleomycin tattooing, 1.5 IU/mL	92, 88	NA	Effective; may cause pulmonary fibrosis, cutaneous reactions	Review of case study, control trial
Postsurgical interferon-α2b, 1.5 million IU, intralesional injection bid for 4 days	30–50	8–19	Expensive; may cause pruritus, altered pigmentation, pain	Review of multiple case studies
Radiation therapy alone	56 (mean)	NA	Local growth inhibition; may cause cancer, hyperpigmentation, paresthesias	Review of multiple case studies
Onion extract topical gels (Mederma)	NA	NA	Limited effect alone, better in combination with silicone sheeting	Prospective case study

bid, Twice daily; *NA*, not available.

Updated from Townsend CM, Beauchamp RD, Evers BM, Mattox KL, Sabiston DC. Chapter 6: Wound healing. In: Townsend CM, ed. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice.* Elsevier; 2022; Juckett G, Hartman-Adams H. Management of keloids and hypertrophic scars. *Am Fam Physician.* 2009;80:253-260.

healed. An inverse relationship between TNF-α and essential growth factors, such as EGF and PDGF, has been demonstrated.

Chronic wounds typically exhibit powerful proinflammatory stimuli, including bacterial colonization, necrotic tissue, foreign bodies, and localized tissue hypoxia. Tissue edema is significant, and the distance between capillaries is increased, reducing oxygen diffusion to individual cells. Chronic wounds typically have high bacterial counts, which stimulates an inflammatory host response, with polymorphonuclear neutrophils (PMNs) expressing reactive oxygen species (ROS) and proteases, resulting in a highly pro-oxidant environment. Disturbed oxidant balance is the likely key factor in the amplification and persistence of the inflammatory state in chronic wounds. In addition to direct cell membrane and ECM protein damage, PMN-derived ROS, such as superoxide,

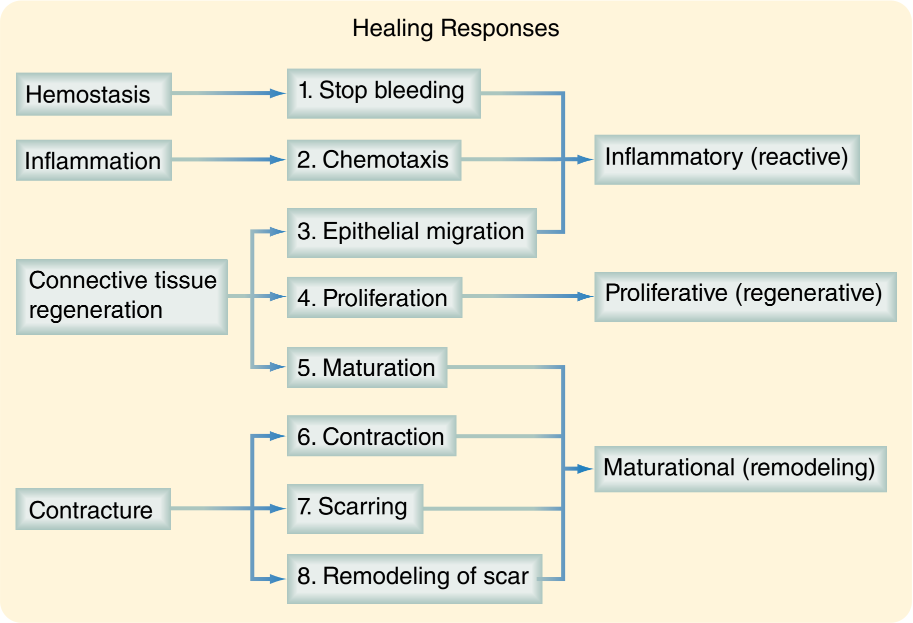

FIGURE 45.6 Schematic diagram of the wound-healing continuum.

hydroxyl radicals, and hydrogen peroxide, can selectively activate signaling pathways, leading to the activation of transcription factors that control the expression of proinflammatory chemokines and cytokines such as IL-1, IL-6, and TNF-α and proteolytic enzymes such as MMPs and serine proteases. Bacterial components, including formyl methionyl peptides and extracellular adherence proteins, may also contribute to the upregulation of the inflammatory response.

The amount of normal wound ECM is determined by a dynamic balance among overall matrix synthesis, deposition, and degradation. A defining feature of chronic wounds is the unbalanced activity that overwhelms tissue-protective mechanisms. Although activated keratinocytes, fibroblasts, and endothelial cells have been shown to increase the expression of proteases, incoming neutrophils and macrophages are considered to be the source of proteases, particularly cathepsin G, urokinase-type plasminogen activator, and neutrophil elastase. The expression and activity of gelatinases (MMP-2, MMP-9), collagenases (MMP-1, MMP-8), stromelysins (MMP-3, MMP-10, MMP-11), and membrane-type MMP (MT1-MMP) are upregulated in chronic venous ulcers.

Proinflammatory cytokines are potent inducers of MMP expression in chronic wounds, also reducing TIMP expression, resulting in a relative excess of MMP activity. For example, α_1-proteinase inhibitor, α_2-macroglobulin, and components of the ECM, such as fibronectin and vibronectin, are downgraded or inactivated within chronic wounds. Growth factors, such as PDGF and VEGF, are also targeted when there is excess protease activity.

Other proposed causes for wound chronicity include keratinocyte hyperproliferation at the periphery, resulting in inhibition of fibroblast and keratinocyte migration and apoptosis. Fibroblasts have altered morphologies, slower rates of proliferation, and less responsiveness to applied growth factors. The ratio of CD4 to CD8 cells is significantly lower in chronic wounds and is likely to be important in the pathogenesis of diabetic ulcers. Finally, chronic wounds have reduced levels of important growth factors (fibroblast growth factor [FGF], EGF, and TGF-β), likely secondary to degradation by excessive proteases or trapping by ECM molecules.

Chronically inflamed wounds are susceptible to neoplastic transformation. Squamous cell carcinoma (Fig. 45.8) was originally reported in chronic burn scars by Jean Nicholas Marjolin. Nowadays, any chronic wound that develops malignant degeneration can be referred to as a *Marjolin ulcer.* Chronic osteomyelitis, pressure sores, venous stasis ulcers, and hidradenitis may also develop neoplastic change. Biopsies should be performed in cases of chronic wounds that appear clinically atypical. This condition is attributed to a long-standing cyclic poor wound-healing pattern based on inflammation, ulceration, and irritation. Cutaneous wounds may first exhibit pseudoepitheliomatous hyperplasia—a premalignant condition. Such a diagnosis on biopsy should prompt additional biopsies to exclude squamous cell carcinoma, which may already be present in other areas of the wound.

Causes of Abnormal Wound Healing

Hypoxia

Molecular oxygen is essential for collagen formation. Ischemia secondary to cardiac failure, arterial disease, or simple wound tension prevents adequate local tissue perfusion. Under hypoxic conditions, energy derived from glycolysis may be sufficient to initiate collagen synthesis, but the presence of molecular oxygen is critical for posttranslational hydroxylation of the prolyl and lysyl residues required for triple-helix formation and cross-linking of collagen fibrils. Although mild hypoxia stimulates angiogenesis, this essential step in collagen fibril assembly proceeds poorly when the partial pressure of oxygen (PO_2) becomes less than 40 mm Hg. Optimal PO_2 for collagen synthesis may be present at the periphery of the wound, but the center may remain hypoxic. The partial pressure of oxygen in chronic wounds tends to be decreased, ranging from 5 to 20 mm Hg compared with the 35 to 50 mm Hg found in healthy tissue. Most physiologic routes in the repair cycle are oxygen dependent; thus, several steps in the repair process are halted or decreased in hypoxic scenarios.[10]

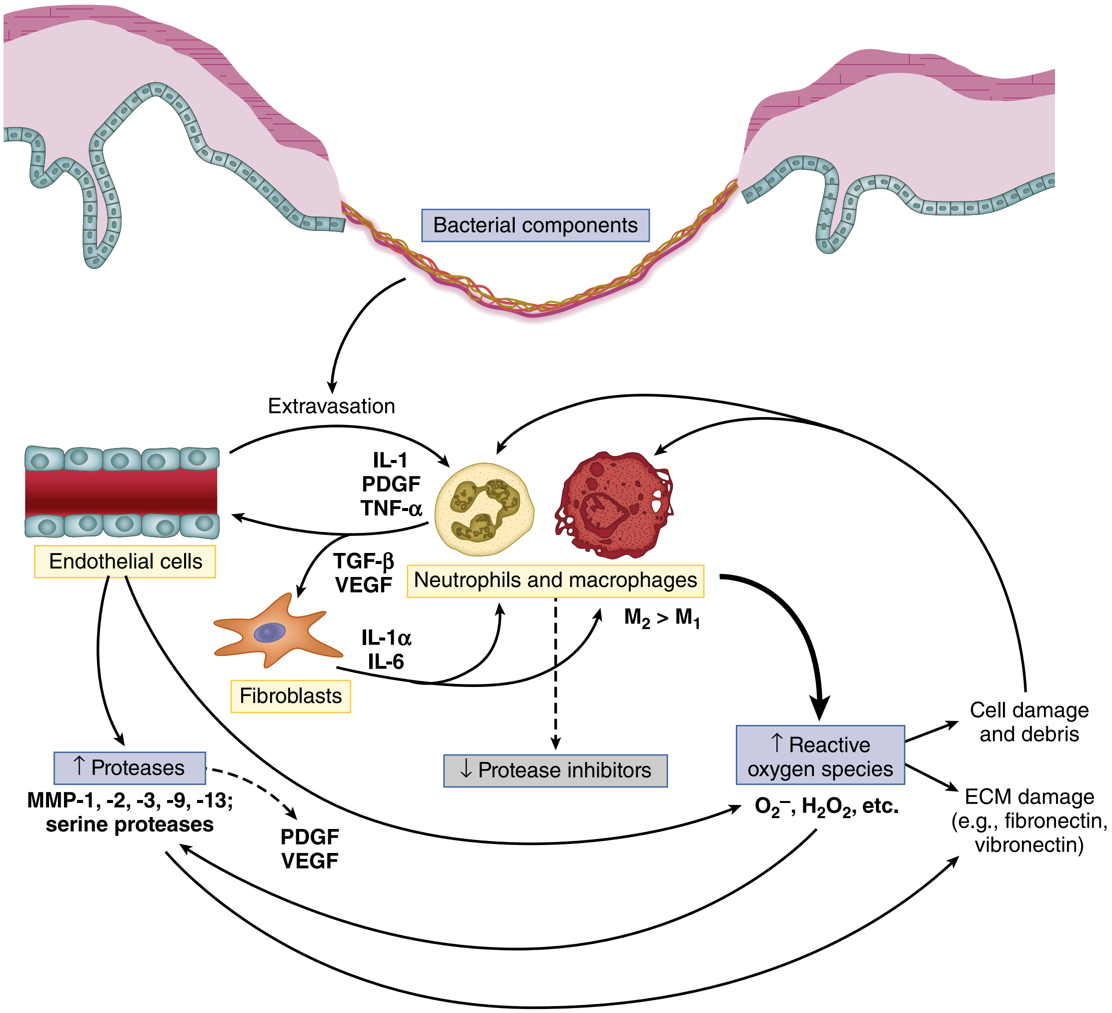

FIGURE 45.7 Mechanisms involved in the development and persistence of chronic wounds. Chronic wounds do not adequately complete the "normal" phases of wound healing. A state of chronic inflammation develops as many of the cells recruited to the wound in the proliferative phase of healing adopt a proinflammatory secretory profile. Inflammatory cells, particularly neutrophils and macrophages (M1 phenotype > M2 phenotype), persist in the wound, creating a highly pro-oxidant, protease-rich environment with an abundance of proinflammatory cytokines such as interleukin-1 *(IL-1),* interleukin-6 *(IL-6),* and tumor necrosis factor-α *(TNF-α).* The result is a hostile environment with downregulation of protease inhibitors and direct damage to extracellular matrix *(ECM),* cellular components, and protective growth factors such as platelet-derived growth factor *(PDGF)* and vascular endothelial growth factor *(VEGF).* Reactive oxygen species and proteases, such as matrix metalloproteinases *(MMP-1, -2, -3, -9, -13),* are the most significant deleterious influences. *Solid lines* indicate upregulation, and *dashed lines* indicate downregulation. The width of the line is proportional to the effect of the influence. *H_2O_2,* Hydrogen peroxide; *O_2^-,* superoxide; *TGF-β,* transforming growth factor-β. (From Greaves NS, Iqbal SA, Baguneid M, et al. The role of skin substitutes in the management of chronic cutaneous wounds. *Wound Repair Regen.* 2013;21:194-210.)

The role of anemia in wound healing has long been attributed to be predominantly secondary to hypoperfusion. However, studies evaluating colonic anastomoses in a crystalloid-resuscitated hemorrhagic shock model demonstrated that altered histologic parameters decreased white blood cell infiltration, angiogenesis, fibroblast production, and collagen production, all contributing to delayed wound healing.

Tobacco smoking and consumption of tobacco products cause peripheral vasoconstriction and a 30% to 40% reduction in wound blood flow. Elevated levels of serum carbon monoxide inhibit enzyme systems necessary for oxidative cellular metabolism. Nicotine also inhibits platelet prostacyclin, promoting platelet adhesiveness, thrombotic microvascular occlusion, and tissue ischemia. Tobacco use inhibits endothelial cell and fibroblast function, nitric oxide (NO) synthase activity, VEGF production, fibroblast proliferation, collagen synthesis, and vitamin C levels. Studies in animals suggested that nicotine cessation for 14 days before flap surgery resulted in similar outcomes to controls, although most clinicians recommend complete smoking cessation in human patients for 4 to 6 weeks before elective procedures.

Diabetes

Diabetes mellitus impairs wound healing in several ways. Diabetes-associated large-vessel occlusion and end-organ microangiopathy

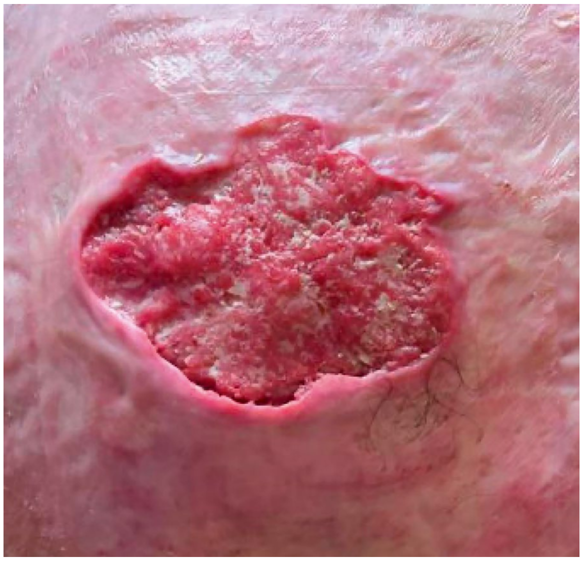

FIGURE 45.8 Squamous cell carcinoma of the back after chronic burn injury.

each lead to tissue ischemia and infection. Diabetic sensory neuropathy leads to repeated trauma and unrelieved wound pressure. Tissue hypoxia can be demonstrated by reduced dorsal foot transcutaneous oxygen tension. The thickened capillary basement membrane decreases perfusion in the microenvironment, and elevated perivascular localization of albumin suggests an increased capillary leak. VEGF upregulation in patients with diabetes is also impaired. Hypoxia is normally a potent regulator of VEGF, but cells from patients with diabetes do not upregulate VEGF expression in response to hypoxia.

Sensory neuropathy in patients with diabetes predisposes them to repeated trauma. They are susceptible to infection because of an attenuated inflammatory response, impaired chemotaxis, and inefficient bacterial killing. Infection further increases local tissue metabolism, placing an additional burden on the tenuous blood supply and amplifying the risk for tissue necrosis. Lymphocyte and leukocyte function are impaired. Collagen degradation is increased, whereas collagen deposition is impaired. Collagen is brittle secondary to glycosylation in the ECM. In addition, collagen glycation diminishes focal adhesion formation between fibroblast and matrix, resulting in decreased fibroblast migration.

Hyperglycemia causes increased advanced glycation end products, which induce the production of inflammatory molecules (TNF-α, IL-1) and interfere with collagen synthesis. High glucose exposure also results in changes in cellular morphology, decreased proliferation, and abnormal differentiation of keratinocytes. Decreased chemotaxis, phagocytosis, bacterial killing, and reduced heat shock protein expression impair the early phase of wound healing in patients with diabetes. Altered leukocyte infiltration and wound fluid IL-6 characterize the late inflammatory phases of wound healing in these patients. Growth factors are abnormally expressed and degraded rapidly in wound fluids as a result of increased insulin-degrading enzyme activity. Insulin-degrading enzyme activity in wound fluid is positively correlated with hemoglobin A1c levels. Elevated MMPs are seen in diabetic wounds in a pattern similar to chronic wounds. Finally, there is increasing evidence that resident cells in chronic wounds undergo phenotypic changes that render them senescent and impair their capacity for proliferation and movement.

Approximately 15% of patients with diabetes will develop DFU disease, which precedes over 80% of diabetes-related lower limb amputations. Recent literature reports decreased levels of IGF-1 and TGF-β in human and animal hyperglycemic models, which resulted in altered granulation and epithelialization.[11] Additionally, an abnormal relationship between VEGF caused by unstable hypoxia-inducible factor-1α (HIF-1α) in diabetic mice models was associated with dysregulated angiogenesis.[11]

Genetic pathways that may play a role in the pathophysiology of diabetic ulcers and chronic nonhealing wounds. Epigenetic alterations, including microRNA-expression patterns, impair normal inflammatory mediators release; modulate macrophage, monocyte, and fibroblast function; and derange inflammatory response in diabetic wounds.

Ionizing Radiation

Ionizing radiation has its greatest effect on rapidly dividing cells in phases G2 through M of the cell cycle. Injury to keratinocytes and fibroblasts impairs epithelialization and formation of granulation tissue during wound healing. Radiation injury in endothelial cells results in endarteritis, atrophy, fibrosis, and delayed tissue repair. Repetitive radiation injury results in repetitive inflammatory responses and ongoing cellular regeneration. Early side effects include erythema, dry desquamation, skin hyperpigmentation, and local hair loss. Late effects include skin atrophy, dryness, telangiectasia, dyschromia, hypopigmentation, fibrosis, and ulceration. The inflammatory and proliferative phases may be disrupted by the early effects of radiation. Affected factors include TGF-β, VEGF, TNF-α, IFN-γ, and cytokines such as IL-1 and IL-8. These cytokines are overexpressed after the radiation injury, leading to uncontrolled matrix accumulation and fibrosis. NO, which induces collagen deposition, is decreased in irradiated wounds; this may explain the impaired wound strength seen in irradiated wounds. Decreased MMP-1 may contribute to inadequate soft tissue reconstitution (Table 45.3).

Keratinocytes, which are crucial for wound epithelialization, demonstrate a shift in expression from the high molecular keratins 1 and 10 to the low molecular keratins 5 and 14 after radiation injury. In nonhealing ulcers, these cells display decreased expression of TGF-α, TGF-β_1 FGF-1, FGF-2, KGF, VEGF, and hepatocyte growth factor (HGF). Expression of MMP-2, MMP-12, and MMP-13 is elevated in irradiated human keratinocytes and fibroblasts. Fibroblasts play a central role in wound healing

TABLE 45.3 Possible Key Wound-Healing Factors Affected by Radiotherapy With Respect to the Phases of Wound Healing

PHASES OF WOUND HEALING	FACTORS AFFECTED BY RADIATION THERAPY
Inflammation	TGF-β, VEGF, IL-1, IL-8, TNF-α, IFN-γ
Proliferation	TGF-β, VEGF, EGF, FGF, PDGF, NO
Remodeling	MMP-1, MMP-2, MMP-12, MMP-13, TIMP

EGF, Epidermal growth factor; *FGF,* fibroblast growth factor; *IFN-γ,* interferon-γ; *IL-1, -8,* interleukin-1, -8; *MMP-1, -2, -12, -13,* matrix metalloproteinase-1, -2, -12, -13; *NO,* nitric oxide; *PDGF,* platelet-derived growth factor; *TGF-β,* transforming growth factor-β; *TIMP,* tissue inhibitors of metalloproteinase; *TNF-α,* tumor necrosis factor-α; *VEGF,* vascular endothelial growth factor.

Adapted from Haubner F, Ohmann E, Pohl F, et al. Wound healing after radiation therapy: review of the literature. *Radiat Oncol.* 2012;7:162.

through the deposition and remodeling of collagen fibers. However, in irradiated tissue, fibroblasts generate disorganized collagen bundles from dysregulation of MMPs and TIMP. Because TGF-β regulates MMPs and TIMP, it may be of particular relevance to radiogenic ulcers (see Table 45.3).

Strategies for treating problematic radiogenic ulcers include physical therapy with massage, antioxidants, topical treatments, standard wound care, negative-pressure wound therapy, and optimized blood and oxygen delivery. Hyperbaric oxygen (HBO) therapy may improve tissue oxygen partial pressure in the treatment of osteoradionecrosis via increased capillary density and more complete neovascularization. HBO therapy is used clinically in patients with chronic diabetic ulcers and wound-healing complications after radiotherapy, and randomized clinical trials have demonstrated efficacy when HBO therapy was used in conjunction with standard wound care in cases of recalcitrant, diabetic, and potentially radiation-induced wounds.[12]

Recently, autologous fat grafting (AFG) has been described as a treatment for radiation wounds. The study demonstrated improved vascularization and decreased fibrosis in tissue biopsies after grafting.[13] Likewise, irradiated animal models had decreased collagen disorders and improved skin perfusion after undergoing fat grafting.[13] Although AFG has mostly been tested in breast, head, and neck cases, it continues to be a widely studied area of radiation-induced skin fibrosis.[13]

Aging

Older patients are more likely to experience delayed healing and surgical wound dehiscence. The aging epidermis has fewer Langerhans cells and melanocytes and flattening of the dermal-epidermal junction. Keratinocyte proliferation is reduced, and the turnover time is increased by 50%. The dermis has fewer fibroblasts, macrophages, and mast cells; reduced vascularity; and less collagen and GAGs. There is a quantitative imbalance between collagen production and degradation and a qualitative alteration of the remaining collagen, which has fewer ropelike bundles and shows greater disorganization. Skin elasticity is decreased because of altered elastin morphology. Diminished light touch and pressure-reduced nociceptive receptors, together with dermal atrophy, increase susceptibility to injury by mechanical forces. Immunosenescence (reduced Langerhans cells and fibroblast activity) impairs wound healing and increases the likelihood of chronic wounds. Microvascular disturbances predispose to ischemic ulcers. Finally, there is reduced sebum secretion and vitamin D_3 production.

Dysregulation of ECM components, including MMPs, decreased reepithelialization, depressed collagen synthesis, impaired angiogenesis, and decreased growth factors (especially proangiogenic FGF-2 and VEGF), have been seen in elderly animal studies. Impaired macrophage activity (reduced phagocytosis and delayed infiltration) and impaired B-lymphocyte activity also have been demonstrated in animal studies. Treatments that target age-deficient mechanisms, such as the reduced expression of superoxide dismutase 1 in situations with high oxidative stress, and the identification of overexpressed micro-RNAs that delay epithelialization and replenishment of hormonal disbalances expected with aging are trending in the literature.[14]

Malnutrition

Protein catabolism delays wound healing and promotes wound dehiscence, particularly when serum albumin levels are less than 2.0 g/dL. Protein supplements can reverse this deficiency. Vitamin deficiencies affect wound healing primarily as a result of their effect as cofactors. Delayed healing can occur 3 months after vitamin C deprivation and can be reversed by supplements of 10 mg/day and no more than 2000 mg/day. Deficiency of vitamin A impedes monocyte activation and deposition of fibronectin, affecting cellular adhesion, and impairs TGF-β receptors. Vitamin A contributes to lysosomal membrane destabilization and directly counteracts the effect of glucocorticoids. Vitamin K deficiency limits the synthesis of prothrombin and factors VII, IX, and X. Vitamin K metabolism is impeded by antibiotics; patients who have chronic or recurrent infections need to have clotting parameters checked before surgical procedures are performed.

Zinc is a necessary cofactor for RNA polymerase and deoxyribonucleic acid (DNA) polymerase. Zinc deficiency impairs early wound healing, but it is rare except with large burns, severe polytrauma, and hepatic cirrhosis. Iron deficiency anemia is a debatable cause of delayed wound healing. Although ferrous ion is a cofactor needed to convert proline to hydroxyproline, reports are conflicting regarding the effects of acute and chronic anemia on wound healing. Mehl and colleagues evaluated the use of an oral nutritional supplement containing arginine; proline; vitamins A, C, and E; zinc; and selenium in chronic wounds.[15] In the study, a significant reduction in the surface area of the wound was described.[15] In general, patients should have a well-rounded diet consisting of adequate protein intake and caloric value plus vitamin and mineral supplementation.

Regarding the route of nutritional supplements, a recent meta-analysis determined that the systemic route for supplementation was more effective than the topical. Nutritional supplementation was favorable as an adjunct to medical treatment, according to Ye and colleagues.[16]

Drugs

Some exogenously administered drugs directly impair wound healing. Chemotherapeutic agents, such as doxorubicin (Adriamycin), nitrogen mustard, cyclophosphamide, methotrexate, and bischloroethylnitrosourea, are potent wound inhibitors in animal models and interfere with uncomplicated wound healing clinically. They reduce mesenchymal cell proliferation, platelet and inflammatory cell counts, and availability of growth factors, particularly if given preoperatively. Tamoxifen, an antiestrogen, decreases cellular proliferation, with a decrease in wound-breaking strength that is dose dependent and may be secondary to decreased TGF-β production. Glucocorticosteroids impair fibroblast proliferation and collagen synthesis, resulting in decreased granulation tissue formation. Recently, Polcz and colleagues described the reversal of the inhibitory effects of antiinflammatory steroids by using vitamin A.[17] This component was found to promote cell turnover, promote ECM components, and enhance the role of fibroblasts.[17] Diminished wound-breaking strength caused by exogenous steroids is time and dose related. High doses of nonsteroidal antiinflammatory drugs have been reported to delay healing, but doses in the therapeutic range are unlikely to have an effect.

Microbiology of Chronic Wounds

Although microorganisms are ubiquitous, human epithelia generally prevent infections in healthy individuals, aside from injuries that disrupt the protective barrier provided by skin. However, chronic wounds tend to occur in those with impaired wound-healing mechanisms. Briefly, mechanisms that cause impaired wound healing involve dysfunction in regeneration and immunologic or physiologic responses. Thus, the burden of persisting health conditions such as type 2 diabetes and obesity as well as the aging process, provide an opportunity for infectious processes to occur. The International Wound Infection Institute functionally defined a wound infection as the invasion and proliferation of microorganisms in a wound to a degree invoking a local and/or systemic response in the host.[18] However, there is not an exact understanding as to why some wounds develop acutely, whereas others develop chronically.

At the local level, microorganisms cause tissue damage and further impede the wound-healing process. In chronically nonhealing wounds that are typically hindered by hypoxia, microbial metabolism further depletes local PO_2. Yet distinctions need to be made among microbial organisms because different phenotypes exhibit unique effects and warrant tailored treatment. When considering bacteria, they largely exist within one of two domains, either planktonic bacteria or biofilms. Planktonic bacteria are those that many tend to envision when considering bacteria—freely meandering organisms existing unicellularly as viewed under a microscope. However, bacteria exist predominantly as colonies that form biofilms. A "biofilm" is a heterogeneous collection of distinct microorganism populations existing within a matrix composed largely of exopolysaccharides. These exopolysaccharides grant adherent properties to surfaces. Biofilm formation was previously thought to follow a characteristic three-step process consisting of attachment, maturation of cell populations, and release of bacteria. More recently, researchers have described an expanded five-step process when investigating the biofilm formation of *Pseudomonas aeruginosa*.[19] They describe the cyclic, progressive formation beginning with either a reversible attachment of planktonic bacteria or an irreversible attachment that would lead to two phases of maturation. These maturation phases correspond to the formation of cell clusters (phase 1) and microcolonies (phase 2). After maturation, the complex is poised for the dispersion of cells from the surrounding matrix. Although dispersion appears to lead to the degradation of the matrix, dispersion results in the dissemination and colonization of bacteria to other locations.

Bacteria that colonize the skin largely derive from Acinetobacteria, Bacteroidetes, Firmicutes, and Proteobacteria. Interestingly, different locations on the body harbor different bacteria. For instance, anaerobic bacteria show preferential colonization in intertriginous areas such as the groin, axillae, and between digits. In chronic wound infections, bacterial colonization is typically polymicrobial. The pathogens encountered in chronic wounds are heavily influenced by an individual's clinical condition and the nature of the wound. Common pathogens found in chronic wounds include *Staphylococcus aureus,* coagulase-negative staphylococci, *Streptococcus* species, *P. aeruginosa,* and *Enterococcus faecalis,* among others.

Treatment of Chronic Wounds

The management of a chronic wound depends on its etiology. Most of the currently available therapies are slow, labor intensive, and expensive, without any guarantee of healing if all local and systemic factors are not addressed. This is especially worrisome considering the financial burden placed on both individuals and providers. To put matters into perspective, the global chronic wound care market was valued at around $13 billion in 2022, with expectations of a $21-billion increase by 2030.[20] These expected increases largely correlate with the increasing prevalence of chronic diseases such as type 2 diabetes and increased rates of obesity. As such, wound-healing research revealed key structural proteins and molecules in both normal and disordered wound healing as potential targets for future interventions. This research led to the application of topical growth factors to chronic wounds, which, although initially promising, almost universally failed in producing clinically significant wound-healing improvements. The reason for the failure is presumed to be a result of degradation of the growth factors by proteases in the wound fluid, and other treatment options need to be explored. Importantly, this failure highlighted the complexity of wound healing—simply replacing one element is not enough. Many factors need to be synchronized to confer optimal wound-healing benefits.

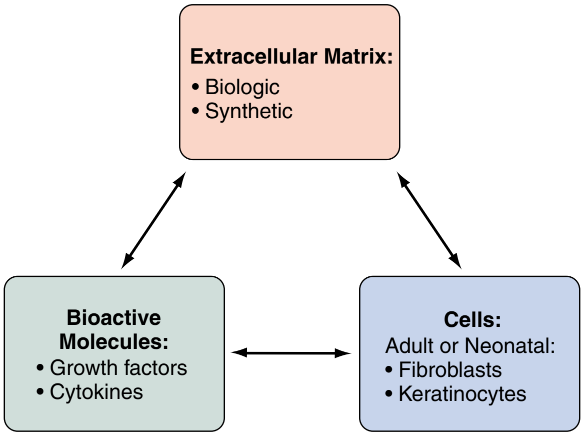

FIGURE 45.9 The "dynamic reciprocity" model of wound healing. Interactions are dynamic because they vary with time and location within the wound site. Products of any one element influence the actions of the others. Inappropriate downregulation of any one element can result in conversion from an acute to a chronic wound. (From Greaves NS, Iqbal SA, Baguneid M, et al. The role of skin substitutes in the management of chronic cutaneous wounds. *Wound Repair Regen*. 2013;21:194-210.)

Skin substitutes, which will be discussed later in the chapter, provide multiple factors that tend to alter the microenvironment of the wound to facilitate and accelerate wound healing. Comparably, split-thickness skin grafting describes the surgical substitution of cutaneous tissue, native epidermis, and partial dermis to assist wound closure. Split-thickness skin grafting has exhibited strong efficacy as a treatment option for acute burn wounds and chronic nonhealing wounds. During the procedure, skin is harvested from the patient and transferred to an adequately prepared wound bed. The graft provides wound coverage by providing a favorable healing environment through the exclusion of pathogenic bacteria and provision of ECM, wound-healing cells (such as keratinocytes and fibroblasts), and bioactive molecules (including cytokines, chemokines, and growth factors) that facilitate wound repair through a process of "dynamic reciprocity" (Fig. 45.9). However, autologous skin grafts occasionally are limited or unavailable depending on the circumstances and clinical setting. Thus, biologic skin substitutes have been used for many years and include, but are not limited to, cadaveric skin allografts and porcine and bovine xenografts; however, these grafts lack significant durability because they do not integrate into the host. As a result, these grafts are associated with rejection and occasionally disease transfer. Be that as it may, they provide an adequate temporary wound cover, limiting complications until autologous grafts or other definitive management strategies are available.

Wound Dressings

Wound dressings have been present since antiquity. They evolved very little for many years until 1867, when Lister introduced antiseptic dressings by soaking lint and gauze in carbolic acid. Since then, many more sophisticated products have become available; however, certain characteristics in wound dressings should be considered in the nonsurgical treatment of a wound (Box 45.2). Wound healing is most successful in a moist, clean, and warm environment. However, not many dressings can provide all of these characteristics simultaneously, although not all wounds require all of them; hence, the choice of dressing should match the prevailing wound conditions.

BOX 45.2 Characteristics of Ideal Dressings

- Create moist environment
- Remove excess exudate
- Present desiccation
- Allow for gaseous exchange
- Impermeable to microorganisms
- Thermally insulating
- Prevent particulate contamination
- Nontoxic to beneficial host cells
- Provide mechanical protection
- Nontraumatic
- Easy to use
- Cost-effective

Adapted from Morin RJ, Tomaselli NL. Interactive dressings and topical agents. *Clin Plast Surg.* 2007;34:643-658.

Two concepts that are critical when selecting appropriate dressings for wounds are occlusion and absorption. Studies have demonstrated that the rate of epithelialization under a moist occlusive dressing is twice that of a wound that is left uncovered and allowed to dry. An occlusive dressing provides a mildly acidic pH and low oxygen tension on the wound surface, which is conducive to fibroblast proliferation and the formation of granulation tissue. However, wounds that produce significant amounts of exudate or have high bacterial counts require a dressing that is absorptive and prevents maceration of the surrounding skin. These dressings also need to reduce the bacterial load while absorbing the exudate produced. Placement of a pure occlusive dressing without bactericidal properties would allow bacterial overgrowth and worsen the infection.

Dressings can be categorized into four classes: (1) nonadherent fabrics; (2) occlusive dressings; (3) absorptive dressings; and (4) creams, ointments, and solutions (Table 45.4). Briefly, nonadherent fabrics are fine-mesh gauze supplemented with a

TABLE 45.4 Types of Dressings

CATEGORY	COMPOSITION AND CHARACTERISTICS	FUNCTION	EXAMPLES	COMMENTS
Nonadherent fabrics	Fine-mesh gauze with supplement to augment occlusive and nonadherent properties, healing-facilitating capabilities, and antibacterial characteristics	Protection, moist environment	Adaptic, Mepitel, Scarlet Red, Telfa, Vaseline gauze, Xeroform, Xeroflo	Scarlet Red, Xeroform, Telfa, Vaseline gauze: hydrophobic, more occlusive; Xeroflo, Mepitel, Adaptic: less occlusive, subject to drainage of fluid into overlying dressing layers
Absorptive				
Gauze	Wide mesh gauze	Exudate removal, maceration prevention	Wide mesh gauze	Not effective when saturated; can be used for wound debridement if in contact with wound
Foams	Hydrophobic polyurethane sheets	Protection, absorb exudate	Allevyn, Curafoam, Flexzan, Lyofoam, Vigifoam	Advantages—comfortable, can expand and conform to wound, easily removed for cleansing Disadvantages—need to be replaced as wounds heal, custom shapes are labor intensive to make, limited protection from bacteria, cannot be used while bathing
Occlusive				
Nonbiologic		Insulation, moisture retention, protective barrier acts against bacteria		
Films	Clear polyurethane membranes with acrylic adhesive on one side	As above	Biooclusive, Hydrofilm, Mefilm, Opsite, Tegaderm, Transeal	Waterproof; permeable to oxygen, carbon dioxide, and water vapor; do not interfere with patient function; allow visualization of wound; nonabsorptive, can leak; require intact skin around wound area; wound contraction may be slowed; removal may disrupt new epithelium
Hydrocolloids	Hydrocolloid matrix (gelatin, pectin, carboxymethylcellulose)	As above; absorbs water from wound exudates, swells, liquefies to form moist gel; facilitates angiogenesis and granulation	Comfeel, Duoderm, Hydrocoll, Nu-Derm, Replicare, Tegasorb	Available as adhesive wafers, paste, powders; similar features as films, but bulkier; more protection, but may interfere more with function

TABLE 45.4 Types of Dressings—cont'd

CATEGORY	COMPOSITION AND CHARACTERISTICS	FUNCTION	EXAMPLES	COMMENTS
Alginates	Cellulose-like polysaccharide fibers derived from calcium salt of alginate (seaweed)	As above; highly absorbent, contact with wound exudates results in hydrophilic gel	Algisite, Algoderm, Kaltostat, Curasorb, Melgisorb, SeaSorb, Alginate, Sorbsan, Suprasorb	Occlusive environment, yet easily removed; hemostatic and flexible; exists in various forms (ropes, ribbons, pads)
Hydrogels	Polyethylene oxide or carboxymethylcellulose polymer and water (80%)	As above; rehydrating agents for dry wounds; little water absorption; facilitate autolytic debridement; smart hydrogels have robust functions	Curagel, FlexiGel, Flexderm, Purilon, Intrasite, Hydrosorb, Hydrotac, Tegagel	Occlusive environment; provides a soothing, cooling effect; available as gels, sheets, impregnated gauze
Biologic		Similar to nonbiologics		
Homograft	Derived from genetically unique humans		Cadaver skin	Temporary dressing; is rejected if left on wound for extended period
Xenograft	Interspecies graft (e.g., pig)		Pigskin	Same as above
Amnion	Human placenta			Good biologic dressing
Skin substitutes	Different compositions		Integra, AlloDerm, Apligraf, Biobrane, TransCyte	Integra—bilayered membrane skin substitute; AlloDerm—acellular cadaveric dermis; Apligraf—living, bilayered, biologic dressing composed of neonatal dermal fibroblasts on collagen matrix
Creams, Ointments, and Solutions				
Antibacterial	Different compositions	Used to treat infected wounds	Acetic acid (gram-negative *Pseudomonas*); Dakin's solution (broad antibacterial spectrum); iodine-containing antibacterials (Iodosorb, Iodoflex, Betadine; broad antibacterial and antifungal spectrum); silver nitrate (broad antibacterial spectrum); mafenide acetate (Sulfamylon; broad antibacterial spectrum); silver sulfadiazine (Silvadene; broad antibacterial, antifungal, and antiviral spectrum); Acticoat (broad antibacterial spectrum)	Acetic acid—impairs wound healing; Dakin's—toxic to fibroblasts; iodine-containing solutions—toxic to fibroblasts, impair wound healing; silver nitrate—treats burns, slows epithelialization, hyponatremia, stains clothes black; mafenide acetate—penetrates eschar, painful application, inhibits reepithelialization, carbonic anhydrase inhibitor; silver sulfadiazine—transient neutropenia, accelerates epithelialization of partial-thickness burns, neovascularization, commonly used for burns; Acticoat—silver-impregnated occlusive dressing, antibacterial activity lasts 3 days
Antibacterial ointments	Different compositions	Used to treat infected wounds; soothing to apply; lubricates wound surface; occlusive; antibacterial activity lasts 12 hours	Bacitracin (gram-positive cocci and bacilli); neomycin (gram-negative) polymyxin B sulfate (gram-negative); Polysporin (polymyxin B, bacitracin); Neosporin (polymyxin B, bacitracin, neomycin); triple-antibiotic ointment (polymyxin B, bacitracin, neomycin)	Neosporin—increased reepithelialization in experimental wounds by 25% compared with wounds with no dressing
Enzymatic	Different compositions; uses naturally occurring enzymes	Removal of necrotic tissue	Sutilains (derived from *Bacillus subtilis*); collagenase (Santyl; derived from *Clostridium histolyticum*); papain (derived from vegetable pepsin)	Sutilains—digests denatured collagen; collagenase—digests denatured and native collagen; papain—effective against collagen in presence of cofactor containing sulfhydryl group; addition of urea doubles enzymatic action of papain
Other	Normal saline wet-to-dry gauze dressing	Removal of necrotic tissue		Nondiscriminating necrotic and newly formed granulation tissue and epithelium removed; can be painful

TABLE 45.5 Hydrogels

HYDROGEL APPLICATIONS	COMMON MATERIAL	FUNCTIONS
Antibiotic delivery	Polyethylene glycol	Prevent infections
Stem cell delivery	Adipose ECM, collagen derivatives, gelatin variations, etc.	Reepithelialization, neovascularization, accelerated wound closure, etc.
Bioactive agent delivery	PEG and heparin, gelatin, alginates, etc.	Accelerated wound closure, advanced granulation formation, vascularization, etc.
Skin substitution	Collagen, gelatin variations	Accelerated wound healing, angiogenesis, tissue regeneration, etc.
Stimuli responsive	Variable	Responsivity to pH, ROS, enzymes, glucose, temperature, photo or magnetic stimulation

ECM, Extracellular matrix; *PEG,* polyethylene glycol; *ROS,* reactive oxygen species.

substance to augment their occlusive properties or antibacterial abilities, such as Scarlet Red, a relatively nonocclusive dressing that is impregnated with O-tolylazo-O-tolylazo-β-naphthol that is used on skin graft harvest sites in burn care. Xeroform is a relatively occlusive, hydrophobic dressing containing 3% bismuth tribromophenate in a petrolatum base, which helps mask wound odors and has antimicrobial activity against *S. aureus* and *Escherichia coli*.

Occlusive dressings provide moisture retention, mechanical protection, and a barrier to bacteria. These dressings can be divided into biologic and nonbiologic dressings. Examples of biologic dressings are allograft, xenograft, amnion, and skin substitutes. An allograft is a graft transplanted between genetically unique humans, whereas a xenograft is a graft, such as pig skin, transplanted between species. Allografts and xenografts are temporary dressings; both will be rejected if left on a wound for an extended period. Amnion is derived from the human placenta and is another effective biologic wound dressing. Initially, these dressings were most often used in the treatment of burn wounds; however, their use has been extrapolated to all other wound etiologies.

Absorptive dressings are useful for wounds with a significant amount of exudate. Leg ulcers can produce 12 g/10 cm^2/24 hours of exudate. The origination of standardized absorptive dressings came with the creation of wide mesh gauze, which, although functional and economical, loses its effectiveness when saturated. Shortly thereafter, foam dressings emerged with absorbent qualities permitting removal of large quantities of exudate while also maintaining a nonadherent quality to prevent disruption of newly formed granulation tissue upon removal. Examples include Lyofoam (ConvaTec, Skillman, NJ), Allevyn (Smith & Nephew, Largo, FL), and Curafoam (Kendall Company, Mansfield, MA). Although beneficial, wound healing beneath absorptive dressings appears to be slower than under occlusive dressings, possibly because of wicking of cytokines from the wound bed or decreased keratinocyte migration.

Hydrogels, insoluble and hydrophilic, are synthetic polymers composed of 70% to 90% water. Their properties maintain moisture and promote increased wound healing. Recent advances in stimuli-responsive hydrogels allow for the release of retained products within the hydrogel in response to particular stimuli in the wound-healing environment. Because of their biochemical and mechanical properties, hydrogels confer better efficacy in the delivery of certain ingredients compared with other creams and topical remedies.[21] With recent developments, hydrogels have been adapted to respond to physical and chemical stimuli such as temperature, pH, ROS, glucose, and light. These advances not only promote wound care in dry chronic wounds, burns, pressure ulcers, and necrotic wounds but also have implications in chronic diabetic wounds as well. The most significant drawback of hydrogels lies in exudate accumulation, which can damage structural integrity and ultimately lead to microbial contamination (Table 45.5).

The final class of wound dressings consists of creams, ointments, and solutions. This is a broad category that extends from traditional materials, such as zinc oxide paste, to preparations containing growth factors. Various categories include dressings with antibacterial properties, such as acetic acid, Dakin solution, silver nitrate, mafenide (Sulfamylon), silver sulfadiazine (Silvadene), iodine-containing ointments (Iodosorb), and bacitracin. Application of these products is indicated when clinical signs of infection are present or if quantitative culture demonstrates more than 10^5 organisms per gram of tissue. The number of available wound products is constantly growing; thus, surgeons must have information about available dressings to aid wound management techniques.

Hyperbaric Oxygen Therapy

HBO therapy uses oxygen as a drug and the hyperbaric chamber as a delivery system to increase PO_2 at the target area. Clinicians use HBO therapy in a myriad of disease processes, including but not limited to severe anemia, carbon monoxide and cyanide poisoning, air and gas embolism, decompression sickness, improvement of skin graft integrity, improvement of flap survival and salvage, crush injuries, traumatic brain injuries, acute thermal burns, necrotizing fasciitis, refractory osteomyelitis, osteoradionecrosis, chronic wounds, hypoxic wounds, and radiation injuries. Recent advances show further evidence for the treatment of cancer, COVID-19, and chronic diabetic ulcers as well.[22] Regardless of the circumstances being addressed, HBO therapy acts as a modulator of tissue injury and promotes tissue regeneration through the upregulation of certain processes related to cellular repair mechanisms while downregulating processes related to tissue damage. HBO therapy acts as a stabilizing force that restores physiologic balance.

When administering HBO therapy, evaluation of the vascular supply to the target is essential. Thus, revascularization before therapy is an important prerequisite to HBO therapy. Generally, the patients most likely to benefit from adjuvant HBO therapy are those who can demonstrate improvement in tissue in the setting of a hypoxic wound while breathing oxygen under the set hyperbaric conditions. The parameters measured to monitor the effects of HBO therapy mainly include transcutaneous oxygen pressure ($TcPO_2$), which assesses wound perfusion and oxygenation. Accordingly, a wound $TcPO_2$ of less than 35 mm Hg in room air indicates a hypoxic wound, whereas an in-chamber

$TcPO_2$ of 200 mm Hg or more suggests a potential benefit from HBO therapy. HBO treatments for hypoxic wounds are usually delivered at 1.9 to 3.0 atmospheric pressure (atm) for sessions of 90 to 120 minutes each, with the patient breathing 100% oxygen during the treatment. Treatments are given once daily, five to six times per week, and should be given as an adjunct to surgical or medical therapies. Clinical evidence of wound improvement should be noted after 15 to 20 treatments.

The importance of oxygen in the wound-healing process has long been a topic of discussion because wound ischemia is the most common cause of wound-healing failure. Ischemia or tissue hypoxia (PO_2 <30 mm Hg) significantly impairs normal metabolic activity and decreases wound healing by impairing fibroblast proliferation, collagen synthesis, and epithelialization. HBO therapy involves inhalation of 100% oxygen at 1.9 to 2.5 atm, which can increase tissue PO_2 10 times higher than usual and reduce complications related to ischemia or tissue hypoxia. Sustaining a high PaO_2 is sufficient to supply the tissue with all its metabolic requirements, even in the absence of hemoglobin. This degree of hyperoxygenation triggers functional and structural changes at the molecular level, yielding the therapeutic action of HBO therapy. The elevated oxygen concentrations after HBO therapy last for 2 to 4 hours after termination of the session, inducing the synthesis of endothelial cell NO synthase and other factors, stimulating angiogenesis, and encouraging granulation tissue formation as well as other beneficial cellular processes. HBO therapy also provides a bactericidal effect, with evidence of the effect shown in a study by Oley and associates that demonstrated significantly decreased bacterial growth after burn injuries.[23] From a physiologic standpoint, oxygen has been reported to stimulate angiogenesis, enhance fibroblast and leukocyte function, and normalize cutaneous microvascular reflexes.

Investigations into HBO therapy described a potential role in treating diabetic wounds. Previous experiments showed increased proliferation of stem cells, upregulated angiogenesis, and improved wound-healing capacity. This is evident in animal studies that analyzed the effects of HBO therapy on rodent cell metabolism, angiogenesis, and wound healing in diabetic wounds. Likewise, one of these investigations demonstrated a potential synergistic effect for HBO therapy when combined with stem cell therapy, paving the way for new horizons in treatment of nonhealing wounds.[24] In addition to improvement in cell metabolism, HBO therapy decreases ROSs and proinflammatory cytokines and promotes matrix synthesis during wound repair. These findings have prompted multiple clinical trials investigating HBO therapy as adjuvant therapy for the treatment of chronic DFUs and prevention of extremity amputation. Older small-scale randomized clinical trials have demonstrated that HBO is a useful adjunctive therapy for diabetic ischemic foot ulcers and reduces the rate of extremity amputation. These findings are supported by a recent systematic review and meta-analysis that investigated 20 randomized controlled trials and 1263 trials regarding the efficacy of HBO therapy on DFUs. This study noted a significantly increased healing rate, decreased healing time, and decreased incidence of major amputation when compared with conventional therapy, although no difference was seen with the incidence of minor amputation.[22] Pasek and colleagues noted similar findings regarding accelerated ulcer healing and also reported decreased intensity of perceived pain with HBO therapy.[25] When compared with other treatments that increase microperfusion in chronic DFUs such as low-intensity laser irradiation (LILI), HBO therapy was found to achieve greater rates of improvement in chronic DFU healing.[26] HBO therapy in conjunction with standard treatment confers greater wound-healing benefits than those seen with standard therapy alone. The efficacy of HBO therapy as an adjuvant for chronic DFUs cannot be ignored, and a similar rationale has led to investigations into its potential in other ulcer types.

HBO therapy has also demonstrated beneficial effects in treating chronic venous ulcers, peripheral arterial disease, and other refractory ulcers. Lalieu and colleagues stated that HBO therapy assisted patients with nonhealing venous leg ulcers in achieving marked or complete wound healing with improvement in perceived pain and overall health scores.[27] Similarly, a systematic review and meta-analysis revealed that HBO therapy combined with surgical management reduced venous ulcer healing time and surface area as well as lowered perceived pain scores. In addition to the efficacy shown in treating chronic venous leg ulcers, HBO therapy has also displayed improved wound healing in ulcers of rare etiologies. A study investigating multiple case series and case reports involving nonhealing ulcers from vasculitis, livedoid vasculopathy, calcific uremic arteriolopathy, and pyoderma gangrenosum suggested that HBO therapy improved healing rates and pain in these cases; furthermore, the study authors recommend that HBO therapy be used in refractory wounds that are unresponsive to standard therapy.[28]

Complications of HBO therapy are caused by the changes in pressure and oxygen. More specifically, adverse effects from elevated atm and PO_2. Adverse effects from increased pressure most commonly manifest as middle ear barotrauma, ranging from tympanic membrane hyperemia to eardrum perforation. Theoretically, however, increased pressure may cause barotrauma within any enclosed, fluid-filled cavities. Adverse effects related to oxygen typically involve pulmonary, neurologic, and ophthalmologic sequelae. Pneumothorax (particularly tension pneumothorax) is far less common than barotrauma but is a potentially life-threatening condition. Other complications associated with increased PO_2 include oxygen toxicity in brain tissue, which manifests as convulsions resembling grand mal seizures. Oxygen toxicity in the lung results from damage from oxygen free radicals to lung parenchyma and airways, which can cause sequelae ranging from tracheobronchitis to full-blown respiratory distress syndrome. Within the eye, oxygen toxicity may cause transient myopia, hyperopia, and other conditions. A recent study shows that the adverse effects associated with HBO therapy tend to present themselves with chamber pressure above 2.0 atm absolute for at least 10 sessions.[29] As such, clinicians and therapists should be keenly alert for the development of adverse effects with repeated HBO therapy sessions. Zhang et al. also revealed a higher incidence of adverse effects for patients with DFUs receiving HBO therapy, documenting the importance of glucose monitoring to prevent hypoglycemic episodes. Absolute contraindications to HBO therapy are (1) uncontrolled pneumothorax, (2) current or recent treatment with bleomycin or doxorubicin (potential aggravation of cardiac and pulmonary toxicity), and (3) treatment with disulfiram (increases risk of developing oxygen toxicity).[29] Relative contraindications include lung pathologies such as obstructive lung disease, anatomic abnormalities such as blebs or bullae, and other occurrences such as recent thoracic surgery and airway or sinus infection, among others.

There have also been developments for HBO therapy in chronic irradiated wounds. Theoretically speaking, HBO therapy would act to enhance radiation therapy in hypoxic tumors, which are typically more resistant to standard radiation therapy. A systematic review of the Cochrane Database concluded that HBO therapy improved outcomes in patients who had undergone radiation in the head, neck, anus, and rectum area while also reducing rates of osteoradionecrosis after teeth extractions.[16] However, the recommendations were based on small, underpowered studies, and further randomized studies are greatly needed to clarify the benefits of this therapy. These results, which concluded that HBO therapy may have promising results in chronic radiation-induced wounds, are consistent with subsequent systematic reviews by Fernandez and colleagues.[12]

Currently, the use of HBO therapy is covered for reimbursement by the Centers for Medicare and Medicaid Services under specific circumstances. Acute conditions regarding wound care include gas gangrene, acute peripheral ischemia, crush injuries, necrotizing infections, and soft tissue radionecrosis. Chronic diagnoses that are reimbursed are preservation of skin grafts, diabetic lower extremity wounds that have failed standard care, and chronic osteomyelitis unresponsive to medical management. Similarly, the most recent European Consensus Conference on Hyperbaric Medicine reviewed the available evidence on the effects of HBO therapy and concluded that it is indicated in open fractures with crush injury, prevention or treatment of osteoradionecrosis of the mandible, soft tissue radionecrosis (e.g., cystitis, proctitis), DFUs, and femoral head necrosis. Despite evidence suggesting the potential benefit of HBO therapy in healing chronic wounds, its cost is high. Patients often travel long distances for daily treatments at great cost to themselves and their families. Although reported protocols for the treatment of ischemic limb ulcers vary significantly, most involve a total cost of $15,000 to $40,000, thus the importance of Medicare and Medicaid reimbursement services. HBO therapy is not recommended as a primary treatment for patients with uncomplicated diabetic or ischemic ulcers. However, in certain complicated cases, HBO therapy may have a role.

Negative-Pressure–Assisted Wound Therapy

One of the most significant innovations in wound management in recent decades was the improvement in negative-pressure–assisted wound therapies (NPWTs) (Fig. 45.10). The application of uniform negative pressure on wounds, along with a capacity to remove extracellular fluid, promotes accelerated healing. Thus, this technique may be used on acute, subacute, and chronic wounds. By applying subatmospheric pressure to wounds, wound vacuums (wound vacs) remove edema, increase local blood flow, and stimulate formation of granulation tissue. Studies demonstrated significant improvement in wound depth in chronic wounds treated with NPWT compared with wounds treated with saline wet-to-moist dressings.[30] In addition, treatment with negative pressure results in faster healing times with fewer associated complications. With this technology, the surgeon is not only capable of immediate wound closure but can also integrate NPWT before and after surgery or even as an alternative to surgery in extremely ill patients.

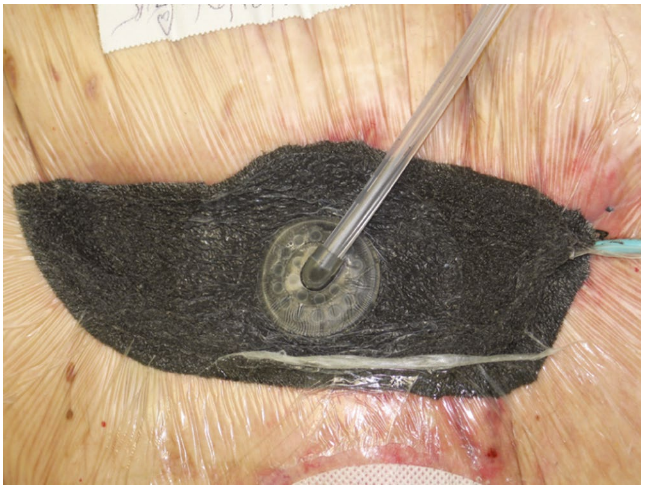

FIGURE 45.10 Negative-pressure–assisted wound closure sponge in place on a patient's abdomen.

The exact mechanism of the improvement in healing with NPWT has continued to be a topic of discussion. Many investigators initially believed that the reason for accelerated wound healing chiefly involved the removal of wound exudates while maintaining moisture within the wound. As originally hypothesized by negative-pressure inception studies from the 1970s, there is a fivefold increase in blood flow to cutaneous tissues with NPWT. Afterward, studies showed an increase in capillary caliber and stimulated endothelial proliferation and angiogenesis. Normandin et al. described the most important mechanisms of NPWT: drainage of inflammatory extracellular fluid, stabilization of wound environment, macrodeformation, and microdeformation.[31] In addition to the removal of exudate for better wound perfusion, the resultant fluid flow applies shear forces and establishes an ion gradient that ultimately leads to a cellular proliferative response. *Macrodeformation* refers to the forced three-dimensional (3D) reduction of wound surface area, whereas *microdeformation* refers to the mechanical forces at the cytoskeletal level that initiate an intracellular cascade leading to gene transcription. The resulting cellular adaptations include cellular proliferation, angiogenesis, and the formation of granulation tissue, as described earlier.

Clinical benefits of NPWT have been demonstrated in randomized controlled trials and include a decrease in wound volume or size, accelerated wound bed preparation and granulation tissue formation, accelerated wound healing, improved rate of graft take, decreased drainage time for acute wounds, reduction of complications, enhancement of response to first-line treatment, increased patient survival, and decreased cost. More recent data have demonstrated improved outcomes in patients with diabetic wounds; ischemic ulcers; and complex vascular, abdominal, gynecologic, and other oncologic surgical wounds with or without contamination.

NPWT has also been directly applied to closed incisions after surgical procedures to prophylactically mitigate surgical site infections (SSIs) and wound dehiscence. Gabriel et al. further investigated this modified NPWT, dubbed *closed-incision negative-pressure therapy* (ciNTP), in preventing postoperative complications related to surgical wounds.[32] They found that NPWT significantly reduces the incidence of SSIs, although they did not find a significant difference in the incidences of dehiscence and hematoma formation. Similar findings have been seen in other recent studies, with evidence finding NPWT superior to debridement or traditional treatment.[33,34] As such, normalization of NPWT could play a vital role in reducing SSIs, which cost billions of dollars annually and lead to further complications and higher mortality rates.

In difficult-to-treat wounds, such as nonhealing diabetic ulcers, NPWT is becoming more widely used as well. Results demonstrated that NPWT led to significant downregulation of IL-1β, TNF-α, MMP-1, and MMP-9 and significant upregulation of

VEGF, TGF-β_1, and TIMP-1 compared with advanced wound care with dressing changes. NPWT significantly increases growth factors, decreases inflammatory cytokines, and normalizes MMP activity, enhancing wound healing. Recent randomized control trials with DFUs displayed the proposed improvement in wound healing with NPWT, showing accelerated reduction of ulcer size with increased granulation tissue; moreover, the studies noted higher rates of complete wound healing, fewer rates of complications, and shorter hospital stays.[33,34] Chen et al. performed a systematic review and meta-analysis supporting said findings on the efficacy of NPWT in treating DFUs, stating that NPTW is equally safe as routine treatment.[35] In addition to treating DFUs, NPWT has shown promise in treating other difficult nonhealing ulcers. A meta-analysis from Song and colleagues using NPWT for stage III/IV pressure injuries noted improved rates of wound healing, shorter healing times, lowered pain scores, and hospital costs.[36]

In addition to the improved outcomes, this treatment represents a significant improvement in cost-effectiveness and has decreased the length of stay after acute and chronic wounds. As previously mentioned in the studies described earlier, NPWT displayed evidence of decreasing costs related to SSIs, chronic DFUs, and other nonhealing injuries. Other literature supports these findings, stating that NPWT offers more overall savings than standard dressings alone.[37] There have been reports of a 78% decrease in hospital stays and a 76% decrease in cost with NPWT. This is substantial, considering the annual financial burden for wound management accounts for over $10 billion in the United States alone.[38] This cost decrease, coupled with efficacy in wound healing from NPWT, has even permitted its use as an at-home treatment for Medicare patients with home healthcare.

Developments of NPWT have further bolstered its widespread use. NPWT with instillation has allowed for the creation of an open-cell foam sponge that allows for periodic installation of the wound bed with sterile fluid, facilitating removal of thick exudate and infectious products. The duration and time interval between each installation can then be adjusted based on the requirements of the wound. The specific solution applied can be variable as well—with installations compatible with normal saline and Dakin solution, among others. Another technologic improvement is the implementation of portable wound vacuum-assisted closure (VAC) devices that are suitable for outpatient treatment. Additionally, the use of one-use disposable devices has become more popular. These devices do not require replacement of the dressing, typically last for a few days, and are particularly useful in the setting of incisional NPWT or treatment of relatively superficial wounds with low exudative fluid output. Of late, there have been developments in noncommercial NPWT alternatives to further minimize costs. A study compared VACs with noncommercial NPWT devices, such as wall suction applied to a sealed gauze dressing (GSUC), Redon drains, and AquaVac.[39] Compared with the VAC, GSUC was the far cheaper option and had comparable granulation tissue formation, effects on wound size, and graft take while also being less painful and time consuming with dressing changes. The AquaVac displayed similar findings, aside from no differences between pain and time required for dressing changes.[39] With noncommercial NPWT alternatives exhibiting similar efficacy at a fraction of the costs, NPWT will be able to have a greater impact in communities lacking sufficient financial resources.

Tissue Replacements

In 1987, the National Science Foundation bioengineering panel defined *tissue engineering* as "the application of the principles and methods of engineering and the life sciences toward the development of biologic substitutes to restore, maintain, or improve function." These principles and methods have been used toward the creation of skin products made of cells, ECM components, or combinations of the two. This tissue-engineered skin has developed and progressed rapidly over the past 25 years, mainly driven by the limitations associated with autografts, and may function by providing the cellular or matrix components that could be necessary for wounds to heal. These new skin substitutes more accurately mimic native tissues to promote sustained healing without rejection. The use of biologic dressings, scaffolds, stem cell therapy, and gene therapy is an example of tissue engineering in which new tissues are created rather than transferred.

Bioengineered skin substitutes can potentially save millions of dollars a year for healthcare delivery services through reduced spending on dressings and treatment of wound-induced complications, particularly in the treatment of venous, diabetic, and pressure ulcers, which form 90% of all chronic wounds. Bioengineered skin substitutes act as protective dressings by limiting bacterial colonization and fluid loss, but they also stimulate healing (Fig. 45.11). Their design is variable and dependent on the layer of skin they are designed to replace.

Skin substitutes can be used in the treatment of both acute and chronic wounds. This wide array of products has advantages and disadvantages. Some, such as Apligraf, are temporary, whereas others offer permanent wound coverage. However, like any medical device, a high cost is often involved. There is not one ideal skin substitute, making this an active realm of research.[40]

Although skin grafts can provide adequate permanent wound coverage, donor site morbidity, pain, scarring, and limitations in donor site locations have pushed researchers into the development of skin substitutes.

Regenerative medicine is playing a key role in new advances in wound care and has provided for the development of many other skin substitutes; these products have been found to advance reconstructive outcomes. These substitutes may be epidermal only or dermal only or may replace full-thickness skin (Table 45.6). They also differ in how they are processed and whether they are animal or synthetically derived. Many classification systems have been devised in the past to categorize the array of products available. One of the most efficient categorizations is based on five different characteristics: cellularity, material, layering, replaced region, and permanence. Each product is described using these terms so that their exact nature is easily understood by clinicians.

Acellular products are, by definition, immunologically inert because they are created by removing all or almost all cellular components from sources such as animal tissue, human amnion, and cadaveric dermis. These types of skin replacements resist shelf storage and can be stored for years, which provides an advantage over cellular skin replacements. Although the production and maintenance of cellular skin grafts are more demanding than the acellular versions, it is thought that the preserved viable cells within these constructs provide unmatched benefits toward healing.

Material-wise, substitutes of human origin are termed *allografts,* whereas those derived from animals are referred to as *xenografts.* Examples of allograft precursors include placenta, amniotic membrane, foreskin, and donated human dermis. In the xenograft category, the use of bovine, porcine, ovine, and most recently, fish skin has been described.

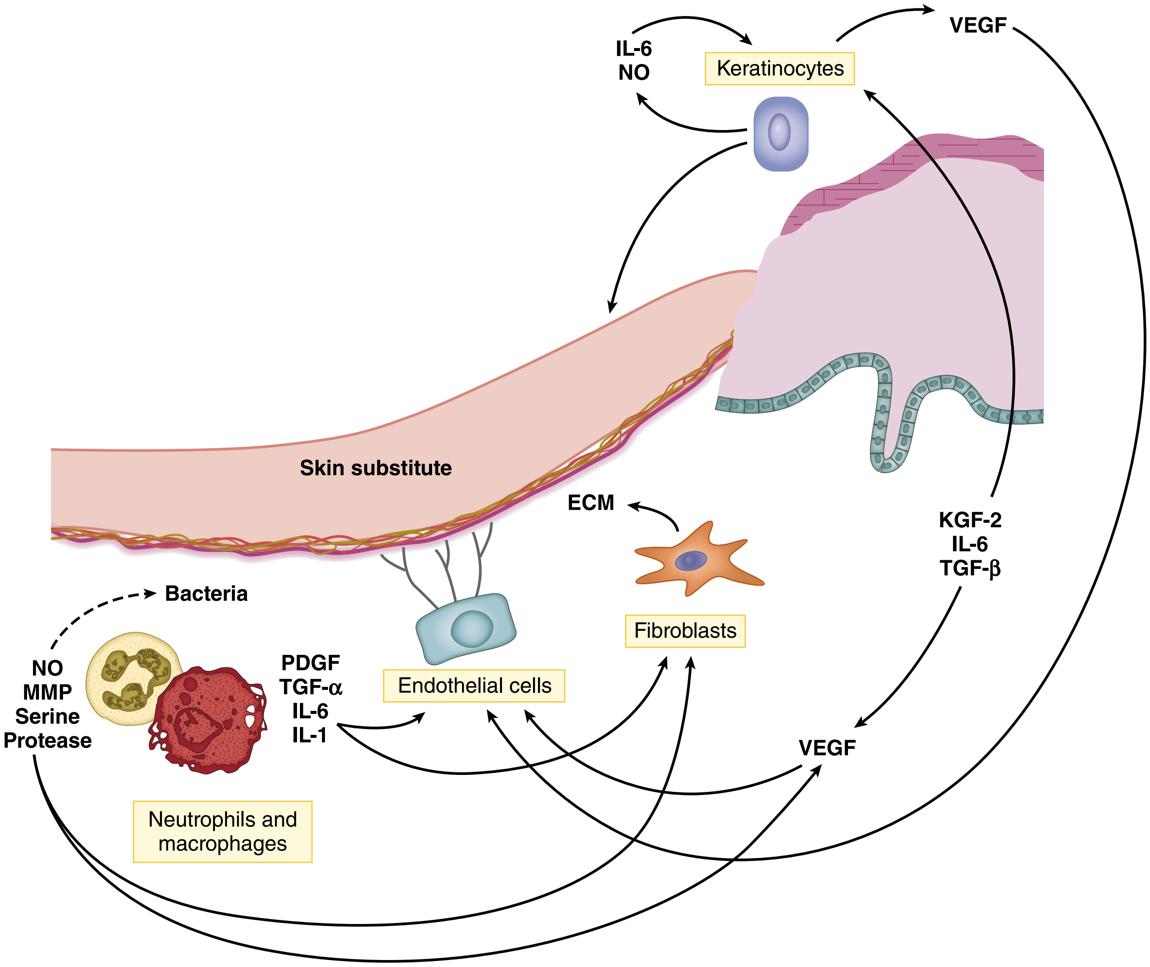

FIGURE 45.11 The effect of skin substitutes in the wound bed. Skin substitutes have variable structures and cellular content. They may be cellular or acellular, but both forms induce the influx of endogenous cells, including fibroblasts, keratinocytes, endothelial cells, macrophages, and neutrophils, into the wound bed. These cells secrete various cytokines and growth factors that stimulate angiogenesis, extracellular matrix *(ECM)* deposition, and reepithelialization via the process of dynamic reciprocity. The skin substitute is replaced by native tissues, eventually resulting in a healed wound. *Solid lines* indicate upregulation, and *dashed lines* indicate downregulation. *IL-1,* Interleukin-1; *IL-6,* interleukin-6; *KGF-2,* keratinocyte growth factor-2; *MMP,* matrix metalloproteinase; *NO,* nitric oxide; *PDGF,* platelet-derived growth factor; *TGF-α,* transforming growth factor-α; *TGF-β,* transforming growth factor-β; *VEGF,* vascular endothelial growth factor. (From Greaves NS, Iqbal SA, Baguneid M, et al. The role of skin substitutes in the management of chronic cutaneous wounds. *Wound Repair Regen.* 2013;21:194-210.)

Regarding the replaced region, epidermal skin substitutes are created by the expansion of patient-derived keratinocytes in the laboratory. The primary role is to provide a protective barrier against microorganisms and prevent fluid loss. These are fragile constructs that promote the proliferation of keratinocytes. Given their thin nature, they are attached to a carrier material to facilitate application to the wound. One of the major drawbacks of cultured autografts is that they are extremely thin, susceptible to shearing forces, and experience a great deal of contraction; thus, not many epidermal-only skin substitutes are available on the market. Two available options are as follows:

- Epicel is one of the cultured epidermal autografts used solely as an epidermal replacement. To obtain Epicel, keratinocytes from the patient are inactivated and harvested into sheets. The layer of keratinocytes is then held together by a reinforcement-carried layer.
- MySkin is an epidermal skin substitute with a different presentation and delivery mechanism. MySkin is a solution delivered as a spray.

Dermal substitutes are based on a structural 3D matrix material that behaves similarly to ECM and may incorporate cells or bioactive molecules. Delivering these key factors to the wound bed may provide the necessary stimulus to rebalance the wound microenvironment in favor of healing. The epidermis is removed, and the dermal ECM is preserved to act like a scaffold for cell migration. Thus, these constructs provide a physiologically similar framework for healing. Most dermal substitutes are acellular and have high macroporosity to promote cell migration and revascularization. Some examples of dermal substitutes are as follows:

- AlloDerm is an allograft acellular, single-layer, temporary dermal substitute derived from cadavers; it has been used a great deal in breast reconstruction.

TABLE 45.6 Tissue Replacements: Epidermal, Dermal, and Bilayer

TYPE	DESCRIPTION	CELLULARITY AND MATERIALS	EXAMPLES
Epidermal	Protective barrier against microorganisms and prevent fluid loss. Require carrier materials and are fragile.	Cellular Human keratinocytes	Epicel, Epidex, and MySkin
Dermal	Structural three-dimensional matrix material that behaves similarly to ECM and may incorporate cells or bioactive molecules. The dermal extracellular matrix is preserved in this constructs and acts like a scaffold for cell migration. Thus, dermal replacements provide a physiologically similar framework for healing.	Acellular and cellular Human derived: dermis and amnion chorion Animal derived (*in italics*): ovine, bovine, porcine, fish Other: synthetic (underlined)	Affinity Human Amniotic, FloGraft Amniotic, Grafix, GrafixPL Prime, AlloWrap, AltiPlast, AmnioBand, Amnioexcel, AmnioFill, AmnioFix, Amniomatrix, Artacent, Bio-ConneKt, BioDFactor, BioDFence, Biovance, Cellesta, CollaWound, Cygnus Amnio Patch, Dermavest, EpiCord, EpiFix, FlowerAmnio Patch, Genesis, Integra BioFix, Interfyl, Neox Wound, NuShield, PalinGen, Restorigin, Revita, WoundEx, Xwrap, AlloDerm, AlloPatch, AlloSkin, Coll-e-derm, Dcell, DermACELL, DermaPure, DermaSpan, FlowerDerm, GammaGraft, GraftJacket, hMatrix ADM, InteguPly, Matrix HD, *Talymed, Excellagen, Helicoll, Integra Avagen, Integra Flowable, MatriDerm, PriMatrix, Endoform, Cyta wound, EZ Derm, Geistlich Derma, MicroMatrix* *MiroDerm, Nevelia, Oasis, Ologen, PuraPly, Theraform, Puracol, Kerecis*, Hyalograft, NovoSorb, Hyalomatrix, Restrata, Dermagraft
Bilayer	Represent a combination of features seen in epidermal and dermal models. These components are the most complex because of their physiologic resemblance to natural tissue. Strong ability to induce angiogenesis.	Acellular and cellular Human, bovine, and porcine derived	AltiPly, Apligraf,* OrCel,* SkinTE, Stratagraft, TheraSkin, *Biobrane*

All are human derived except those in *italics*, which are animal derived, and those that are underlined, which are synthetic.

*Indicates both human and animal derived.

Adapted from Bay C, Chizmar Z, Reece EM, et al. Comparison of skin substitutes for acute and chronic wound management. *Semin Plast Surg.* 2021;35(3):171-180.

- Integra is an acellular dermal substitute composed of sheets of bovine tendon and shark GAGs developed in the 1970s. Although initially developed for tissue coverage in burn patients, it is currently used for coverage of areas nonamenable to skin grafting, such as joint capsules, bone, and tendon from all etiologies.
- Kerecis is an acellular xenograft derived from North Atlantic cod fish. Unlike other skin substitutes, the molecular components and structural characteristics of nature are kept intact. Fish derivatives contain proteoglycans, glycoproteins, collagen, elastin, fibronectin, and omega-3 polyunsaturated fatty acids in a high-tensile-strength and rapidly degradable matrix; these components are thought to act synergistically in tissue repair. Recently, Yoon et al. demonstrated faster reepithelialization and cell proliferation with Kerecis compared with a bovine collagen skin graft.[41]
- In recent years, NovoSorb Biodegradable Temporizing Matrix (BTM) has become more widely used in the reconstruction of complex wounds. BTM is a synthetic dermal matrix consisting of a biodegradable polyurethane open foam cell that faces the wound surrounded by an overlying nonbiodegradable sealing membrane. The open matrix facing the wound permits the infiltration of cells and cellular products and functions as a scaffold in the formation of neodermis. The nonbiodegradable sealing membrane functionally provides a means of physiologic wound closure but also contains microfenestrations in the membrane to stave off accumulation of debris that would otherwise disrupt the integrity of the matrix. BTM application occurs in two stages. First, BTM is applied and secured to a clean wound bed, allowing cells and vascular elements to integrate and form a vascularized neodermis. This integration usually occurs over the course of a few weeks. After adequate integration and consolidation, the overlying nonbiodegradable membrane is removed and is promptly replaced with a split-thickness skin graft over the defect. The applications for NovoSorb BTM are robust. Indications include both partial- and full-thickness wounds, surgical wounds, traumatic wounds, and chronic ulcers. Recently, studies have touted BTM efficacy in reconstructing DFUs as well.[42] Contraindications for BTM application include wounds that require debridement, such as necrotic wounds or devitalized tissue as well as wounds that are infected.

Bilayer materials represent a combination of features seen in epidermal and dermal models. These components are the most complex because of their physiologic resemblance to natural tissue. In vitro studies support the use of bilayer materials over single-layer substitutes based on their strong ability to induce angiogenesis. Different constructs with cellular and acellular components have been released to the market as well as both animal and human-derived composites:

- Biobrane, for instance, is an acellular bilayer that replaces full-thickness skin and is composed of silicone, nylon mesh, and porcine collagen.
- StrataGraft is an allogenic cellularized bilayer substitute that completed a phase III multicenter trial in the burn wound care setting in 2021. This construct is composed of human fibroblasts embedded in a collagen gel. As of now, it has been shown to decrease the area of required autografting and produces results comparable to those of autografts.

Given the steep influx of research, tissue engineering is a rapidly growing and changing field. Over 70 different types of skin substitutes have been released in the market, and many more are currently being studied. Although the literature compares the characteristics of these constructs between each other, it's the distinctive qualities of the wound and the patient that determine the best fit.

Bioengineering: Gene and Stem Cell Therapy

Bioengineered skin substitutes can potentially save millions of dollars a year for healthcare delivery services through reduced spending on dressings and treatment of wound-induced complications, particularly in the treatment of venous, diabetic, and pressure ulcers, which form 90% of all chronic wounds. Bioengineered skin substitutes act as protective dressings by limiting bacterial colonization and fluid loss, but they also stimulate healing (see Fig. 45.11). Their design is variable and dependent on the layer of skin they are designed to replace.

Stem cell therapy is a widely investigated area in wound repair. Somatic cells were initially used to provide a barrier-like protective function for open wounds. Single and bilayer constructs of keratinocytes and fibroblasts were developed for skin regeneration. However, their use was cumbersome and limited to large wounds. MSCs proved to be a superior option because they can differentiate into epidermal and dermal cell lineages while promoting extensive cellular expansion. The administration of stem cells enhances wound-healing processes through direct cell differentiation and molecule-signaling mechanisms. A recent meta-analysis evaluated the efficacy of autologous stem cell therapy from bone, peripheral blood, or adipose-derived MSCs to treat lower extremity chronic wounds secondary to diabetes and peripheral arterial disease.[43] MSCs improved microvascular regeneration, especially when applied intramuscularly.

MSCs are a source of exosomes, which are responsible for transport and communication functions within cells. The majority of exosomes originate from adipose tissue, bone marrow, umbilical cord, and placental MSCs. Exosomes can regulate components in all phases of the wound-healing process. In the inflammatory phase, they act as antiinflammatory molecules, reducing the levels of TNF-α, NO, and cyclooxygenase-2 (COX-2). Their immunomodulatory properties are due to their ability to modulate microRNA in immune cells by promoting negative-feedback mechanisms. During the proliferation phase, exosomes stimulate cell proliferation and inhibit apoptotic pathways. Additionally, they upregulate different types of growth factors, including those associated with angiogenesis. Finally, exosomes endorse collagen and elastin formation and organization during matrix remodeling. Although several in vitro and in vivo studies in different animal models have described the use of exons for wound-healing purposes, data regarding human studies are scant.[44] As described by Ngoc and colleagues, very few human clinical trials have been reported in the wound care setting; other studies have targeted other conditions, such as diabetes and acute respiratory distress syndrome.[44]

Gene therapy has applications in wound healing, as well. Zinc finger nucleases, transcription activator-like effector nuclease (TALEN), and the clustered regularly interspersed short palindromic repeats (CRISPR) system are used for gene editing. Genetically engineered somatic and mesenchymal cells are used to correct gene mutations in chronic skin disorders. Autologous stem cells are genetically modified and transplanted to restore the regular functions of the skin layers. Treatment mechanisms of gene-alteration therapy have been used for cases of epidermolysis bullosa (EB) and recessive dystrophic EB (RDEB).

Electrical Therapy

With advances in tissue engineering, there has been the development of a plethora of innovative wound care treatments aimed at stimulating the cells and chemical mediators needed for wound healing. These treatments include electrical stimulation (ES), therapeutic ultrasound, and vibration therapy (VT) (Table 45.7).

Wounds carry a direct-current electrical gradient that can be used to hasten the healing process. Biochemical studies have found that ES alters gene expression; this then affects the production of chemokines, cytokines, and collagen, promoting an environment favorable for healing. Pathways activated by electrical energy include those of intracellular polyamines, the PI3K/PTEN pathway, and the KCNJ15/Kir4.2 membrane channel.

TABLE 45.7 Electrical Therapy

TYPE	MECHANISM	DETAILS	DEVICES
Electric stimulation	Increased blood flow Promote cell recruitment Muscle stimulation Antibacterial properties Tailored remodeling	Unidirectional or bidirectional direct current or pulsatile current	• Battery-powered units • Challenge 8000A • BLT-5000 series • Portmax 300 electrical • Triboelectric nanogenerator (TENG) • Piezoelectric nanogenerator (PENG)
Ultrasound	Vasodilation Cavitation microstreaming Ultrasound-targeted microbubble destruction Antibiotic synergy	Low (30–40 kHz) and high (1–3 MHz) frequency Bubble size 50 nm to 10 μm	• MIST therapy system • Misonix low-frequency ultrasound • Sonic One • SONOCA device • Qoustic wound therapy system
Vibration therapy	Decrease neutrophils and TNF-α Increase collagen deposit Alters blood flow at skin level	Low-intensity vibration at 45 Hz	• RelaWave Matsuda Microsonics Vibrators • Vibrating plates

TNF-α, Tumor necrosis factor-α.

Several hypothetical mechanisms that explain the effects of ES in wound healing have been described:

- Increase blood flow: ES has been seen to increase blood delivery to tissues, thus facilitating nutrient distribution. When used in rodents, low-frequency ES promoted sensory nerve activation, resulting in vasodilation and accelerated healing.
- Cellular recruitment: ES has been shown to promote the recruitment of neutrophils, macrophages, lymphocytes, and fibroblasts during different stages of the wound-healing process. Readiness of these cells is beneficial for the formation of granulation tissue and the reepithelialization process.
- Remodeling effect: Electrical current encourages the migration of fibroblasts through the PI3K/PTEN pathway. It is also thought to enhance the structure of collagen fibers and their arrangement in the ECM.
- Antibacterial properties: ES has been noted to decrease the bacterial load in wound tissue. Although the exact mechanism is unknown, it is believed to be related to the different polarity fields in direct current. A study evaluating the load of *P. aeruginosa* in rabbits found that the negative pole had antibacterial tendencies.
- Muscle stimulation: It is thought that ES can increase blood flow to affected areas and increase the production of growth factors. In patients with neurologic involvement, ES can be used to facilitate regular muscle contractility to prevent atrophy and skin injuries.

Although there is no conclusive evidence to support any of these hypotheses, ES remains a highly researched alternative in wound healing. Current can be delivered through different methods; however, the most common is directly at the wound level. Two or more electrodes are placed on the skin and then attached to battery-like devices controlled manually. Current is applied either in a direct or pulsatile fashion, with the latter one dividing into monophasic or biphasic settings. Other factors, such as frequency, polarity, amplitude, and exact electrode placement, can be determined based on the wound characteristics. Arora and colleagues presented a meta-analysis of 20 randomized controlled clinical trials evaluating ES plus standard care versus standard care alone for pressure ulcers.[45] On average, ES was administered for 5 hours per week. They concluded with moderate certainty that ES improved the number of ulcers healed. However, the exact area of improvement and time to healing were not able to be estimated. Complications reported in the study included redness and discomfort at the application site.[45]

Different types of devices that deliver ES have been developed. Initially, large and traditional battery-powered units were used; however, these devices had limited availability, poor portability, high cost, and safety concerns. As a result, miniature devices that mimic endogenous electric fields have been the leading trend in research. Nanogenerators (NGs) are self-powered electric systems that transform mechanical energy into electrical energy. These constructs are a wearable and safe alternative to promote fibroblast proliferation and migration in animal models. Although the data regarding NGs are promising, human studies are still lacking.

Ultrasound

Ultrasound, particularly kilohertz ultrasound, causes microstreaming and cavitation as particles are displaced by the vibratory waves. The cavitation protects healthy tissue and promotes the degradation of nonviable tissue. Additionally, the mechanical energy alters the cell membrane through conformational changes in proteins and activation of signaling pathways in cells. For instance, in the proliferative phase of wound healing, it increases macrophage activity and increases collagen production.

Low-frequency (30- to 40-kHz) and high-frequency (1- to 3-MHz) ultrasound are the available types of therapies for chronic wounds. The sound waves from both raise the surface temperature of wounds between 39°C and 41°C, which results in localized vasodilation. Treatment with ultrasound usually lasts 5 to 10 minutes and is done after a topical fluid has been applied as a medium.

A recent meta-analysis compared low-frequency, high-intensity contact ultrasound to standard wound care. High-intensity ultrasound was associated with lower rates of nonhealed DFUs and a higher percentage of ulcer area reduction at 3 months.[46] On a similar note, when low-frequency, low-intensity, noncontact ultrasound was evaluated side by side with nonstandard care, ultrasound treatment was found to be associated with fewer nonhealed ulcers and reduced ulcer area.[46]

Ultrasound debridement is a rather novel term that refers to the disruption of the superficial wound layers to potentiate topical medication application and promote new tissue regeneration. Compared with standard debridement, this technique is noninvasive and moderately painless. This method has been used to treat wounds infected by biofilm by inducing gas bubbles that disrupt the structure of colonizing microorganisms. Given that the range of bubble sizes available is between 50 nm and 10 μm, the desired size must be set based on the goals of the treatment itself. Low concentrations of gas created by the ultrasound result in small bubbles referred to as *nanobubbles*.[47] Greater concentrations of gas create larger bubbles

Ultrasound-targeted microbubble destruction refers to the use of bubbles as a mechanical advantage to shed and potentialize other compounds surrounding the molecules. When used synergistically with antibiotics, this ultrasound technique has been found to decrease levels of bacteria in biofilm significantly. For instance, Darvishi and colleagues depicted how the use of targeted microbubbles, in combination with vancomycin, decreased the levels of *Staphylococcus epidermidis* found on biofilm.[47]

Vibration Therapy

VT has been relevant in orthopedic surgery by promoting bone angiogenesis and mineralization as well as an adjacent therapy to ligament repair treatments. In the wound care field, VT is a rather new concept that is slowly building strength. The benefit behind this approach relies on the tissues' neuromuscular response to vibration waves. Several studies are being carried out with different combinations of mechanical settings (frequency, amplitude, displacement, and peak acceleration) to evaluate the response in wound healing. Most of the current research targeting wound healing is in mice or rat animal models. Currently, the low-intensity vibration (LIV) setting is the most common setting described in the literature regarding tissue repair. VT sessions last 20 to 30 minutes and are carried out once a day and five to seven times per week.

Wano and colleagues evaluated the role of vertical LIV at 45 Hz on male mice with soft tissue wounds.[48] At 7 days, they found decreased neutrophil infiltration and TNF-α levels.[48] At 14 days, there were increased levels of collagen and significantly improved wound closure when compared with the control group.[48] Likewise, when Roberts and associates compared different VT mechanical settings in mice, LIV 45 Hz with a peak of 0.3 was the only setting that resulted in increased angiogenesis, reepithelialization, and granulation tissue.[42]

A recent double-blind study used local VT plantar skin in 10 healthy participants.[49] Blood flow at the level of the first metacarpal was measured after the exposure using wavelet amplitudes.[49] A significant difference in amplitudes of metabolic and neurogenic blood flow was noted in the patients exposed to VT compared with the placebo group, suggesting that local vibrations alter plantar skin blood flow.[49] In 2023, a prospective study that included 40 patients with DFUs was published.[50] VT was used at 47 Hz for 15 minutes daily after standard wound care (off-loading, debridement, and daily monitoring) for 12 weeks in these patients.[50] Syabariyah and colleagues found that participants exposed to VT had a significantly faster wound-healing rate compared with unexposed controls (25 days vs. 33 days).[50] Although the results are promising, the small sample sizes are a limitation. Further research on VT in wound care in human subjects will be required before including VT as a standard of chronic wound care.

SPECIAL CONSIDERATIONS IN ULCER MANAGEMENT

As mentioned before, chronic wounds fail to progress through the normal sequence of the tissue repair process, resulting in a prolonged healing period that impedes the restoration of normal anatomic and functional integrity. The most common types of chronic wounds are pressure ulcers, venous ulcers, and ischemic ulcers.

Pressure Ulcers

Pressure ulcers develop as a result of prolonged pressure over bony prominences such as the sacrum, ischium, and heels. They are common in the elderly and patients with impaired mobility. The prolonged weight-bearing status elevates tissue pressure above capillary perfusion pressure (32 mm Hg), which restricts oxygen delivery. Worsening factors include shear forces, friction, moisture, malnutrition, and impaired blood supply. Great effort should be placed on preventing pressure ulcers by identifying patients at risk and promptly establishing local contact and pressure precautions (e.g., turning schedule). However, if an ulcer has developed, treatment consists of diminishing modifiable detrimental factors that delay wound healing. Specifically, targeting malnutrition with adequate protein intake, decreasing immobility by remedying the underlying condition (if possible) and providing guidance with physical therapy, and correcting hypoperfusion. Once all modifiable factors have been addressed, local and regional fasciocutaneous and musculocutaneous flaps can be considered as an option for wound closure if the lesion persists.[3,8,48,51]

Venous Ulcers

Venous ulcers are the most common type of chronic leg ulcer. They result from incompetent venous valves and calf-muscle pump failure that generate capillary wall distention and leakage of macromolecules, limiting oxygen delivery. Venous ulcers are associated with tortuous varices, dermatitis, and brown pigment discoloration. Treatment is bimodal by addressing the underlying venous insufficiency and providing local wound care of the ulcers. A joint effort with a vascular specialist is required because the specialist provides guidance regarding the management of chronic venous insufficiency. Measures such as compression stockings and leg elevation can be temporizing. Regarding local wound care, the same strategies of chronic wound management apply to this type of ulcer.[3,8,27]

Ischemic Ulcers

Ischemic or arterial ulcers develop in areas where poor circulation exists, such as the toes, lateral feet, malleolus, and pretibial area, commonly affected by atherosclerotic disease. They are associated with factors such as diabetes, hypertension, advanced age, hyperlipidemia, and smoking. Clinical characteristics of these lesions include well demarcated, deep, pale color, poor granulation tissue, and ischemic borders in patients with skin atrophy, lack of hair, delayed capillary refill, and decreased ankle-brachial index (ABI). Patients with ischemic ulcers should be referred urgently to a vascular surgery specialist to determine the need for revascularization and monitor chronic limb-threatening ischemia. The severity of the lesion is determined by the grade of the wound, the level of ischemia, and whether infection is present. Multiple individual patient factors play a role in determining the type of revascularization offered and subsequent antithrombotic, lipid-lowering, and/or antihypertensive medication required. Although local wound care remains the same as that for any other chronic wound, this type of lesion is unlikely to heal properly without adequate perfusion.[3,8,11]

Unfortunately, ulcers are a common, insidious, and morbid type of chronic wound. The cornerstone treatment relies on identifying the triggering factor and addressing it as able. Additional strategies include local wound care, nutrition optimization, and reinforcement of environmental precautions. Nonetheless, these types of wounds continue to be a challenge to healthcare providers.

NEW HORIZONS

Technology has enabled multiple discoveries regarding wound care in the past decades. A greater understanding of the physiopathology of wound healing has opened the way to novel therapies. Coupled with the exponential influx of research in the area, this field is rapidly changing and adjusting to patient's needs. Some of the rising treatment topics for chronic wounds include nanotechnology in both materials and devices, 3D printing, and telemedicine.

Nanomaterials are organic or inorganic components at a nanometer size. They have specific properties and characteristics that apply to medicine, especially wound care. Organic nanomaterials are derived from natural components such as chitosan, collagen, and dendrimers, and inorganic nanomaterials are those made synthetically, for instance, silver, titanium, and copper. Given their nano size, these elements have a high ratio of surface area to volume. Their applications in wound healing rely on nanomaterials whose intrinsic characteristics are beneficial for wound healing or nanomaterials that act as vehicles to deliver medications or other therapeutically advantageous components. Their particular size allows high concentrations of localized drug delivery with fewer side effects than other methods. Nanomaterials can be biodegradable, which is an accepted alternative to other not-so-environmentally-friendly options.

Some examples include carbon nanotubules, which are inorganic biomaterial nanoparticles used to induce platelet aggregation and generate a prothrombotic stage. Carbon nanotubules have been found useful in settings where accelerated hemostatic control is required. Another example is the use of chitosan-based nanomaterials in rat models. Accelerated wound-healing times have been achieved by enhancement of both the proliferative and remodeling stages. Interestingly, chitosan-based components tend to display unique properties that are not common in the individual materials, suggesting a synergistic relationship. Regarding metallic nanomaterials, Vijayakumar and colleagues identified the antibacterial properties of silver, gold, and copper nanoparticles when applied in a polymeric matrix. These minerals are noted to inhibit bacterial growth and accelerate wound healing in diabetic rat models. In general, nanomaterials have demonstrated positive effects in in vitro and in vivo animal studies, especially when acting synergistically in combination.

Another area that is gaining momentum is 3D-printed scaffolds. Unlike premade dressings, these adjust to size, dimension, material, oxygen penetration, and medication release, thus providing a flexible coverage alternative for complex wounds. Additionally, these specialized frames can act as a means for cells, proteins, genes, and drugs to be incorporated into a wound. The layer-by-layer printing nature allows full control of the geometry and structure that best fits the patient in question, with the advantage that certain characteristics, such as porosity, degradability, degree of cell ingrowth, proliferation, or even nutrient transport, can be predetermined. 3D prints resemble autologous tissue by individualizing therapy at its maximum degree. Bioink is an essential component; *bioink* refers to the materials that provide support and structure to the newly created matrix. Common elements of bioink include collagen, polymers, and cells. 3D printing is an area with increasing potential. In combination with nanotechnology, further enhancement of each therapy's wound-healing mechanisms can be obtained. Hu and colleagues evaluated the use of a cryptogenic 3D-printed hydrogel scaffold with exosomes in diabetic wounds in Sprague-Dawley rats.[51] The matrix was composed of decellularized small intestine submucosa, mesoporous bioactive glass, and isolated exosomes.[51] After application of the scaffold, accelerated wound healing by increased angiogenesis and stimulation of organized ECM component deposition was evidenced.[51]

Since the onset of the COVID-19 pandemic, telemedicine has become more widely used in many fields of medicine because many essential healthcare services were disrupted. This is especially true for the treatment of individuals with chronic wounds, where we have seen a shift in management tactics largely as a result of resource scarcity as well as patient and provider limitations. Generally, traditional wound care practices require frequent assessments and stringent therapy regimens, which can be burdensome—especially in this patient population that generally has higher rates of comorbidities. Through the incorporation of telemedicine for wound care treatment, patients suffering from chronic wounds have more expedient access to be clinically assessed. As such, the convenience of telemedicine relieves much of the burden placed on providers, caregivers, and patients, with decreased travel time, scheduling, and costs. Moreover, telemedicine can improve outcomes because it facilitates more prompt assessments and subsequent treatment. Notably, telemedicine has also shown similar safety and efficacy when compared with conventional chronic wound care treatment. Depending on patient and/or provider preferences, telemedicine can be used in a couple of different ways. Telemedicine can function synchronously in real time or function asynchronously with image upload to electronic medical record systems. The flexibility of telemedicine has changed the way we approach wound care management, and further large-scale studies are required to identify its efficacy in other unique clinical settings.

Currently, there are a few types of telehealth models that providers implement. Typically, providers opt toward blended care models as opposed to solely virtual modalities. Blended care models involve conventional in-person care by a practitioner followed by digital monitoring with remote specialists. Purely virtual models were largely implemented due to COVID-19, when providers had to consider exposure risks for themselves and their patients, although it is a viable option if circumstances dictate. Regardless of the modality, telemedicine for wound care is founded on image assessment, phone and/or video consultations, and text-based information delivery. Text-based information is usually accompanied by an electronic medical record system, email, or text messaging. With studies emphasizing the efficacy of telemedicine in wound care, telemedicine could become inherently tethered with chronic wound care management for patients. This notion is exemplified in recent developments such as Project ECHO (Extension for Community Healthcare Outcomes), which aims to provide teleconsulting and telementoring partnerships between specialists and providers in underserved communities, including rural populations. Further evaluation and adaptation of these models are necessary; however, the adoption of telemedicine is becoming more universal.

Wound care is a dynamic area of medicine in which developments occur continuously. The challenging nature of wound care management as well as the substantial psychological and economic burden necessitates further investigation into wound pathogenesis with subsequent innovation in effective treatment options. Moving forward, developments in chronic wound care management will target even more individualized patient needs to improve their quality of life while also reducing costs.

Palliative Care and End of Life

INTRODUCTION

Critical care provides a systems-based algorithm for organ support during critical illness. Surgical critical care adds specific understanding of surgical pathology and its unique corresponding elements of critical illness. Expertise, therefore, allows for earlier recognition and intervention with the critically ill or injured surgical patient. Surgical disease can be further specialized into several distinct populations, including trauma, cardiac, neurologic, and "general" surgical. Surgical critical care, therefore, also has specific training pathways to develop expertise in these specific surgical areas.

Critical care is best delivered in a systems-based approach; therefore, this chapter is organized by organ system. Specific interplay between systems will be discussed where appropriate. A systems-based approach most effectively also involves a multidisciplinary team, with each component supplying critical and complementary expertise. This team commonly includes but is not limited to pharmacy, respiratory therapy, nutritional support, advanced practice nursing, social work, and case management. Finally, although surgical intensivists have broad expertise, involvement of specific specialists with deeper knowledge in specific areas is also common and encouraged. Frequent consultants in this space include infectious diseases, nephrology, and palliative care.

NEUROLOGIC SYSTEM

Pain

The International Association for the Study of Pain (IASP) newly defined pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage."[1] Intensive care unit (ICU) patients have multiple sources of pain, from readily recognized sources, such as procedures, endotracheal tubes, and dressing changes, to less recognized and often overlooked sources, such as suctioning, turning, and other aspects of daily care. Even immobility is a source of pain for patients because it creates musculoskeletal discomfort and neuropathies.

In addition, ICU patients experience hyperalgesia or hypernociception (heightened pain sensation). Studies have shown that proinflammatory cytokines, including interleukin-1 (IL-1) and IL-6, are released after local tissue injury and induce peripheral and central nervous system sensitization, leading to enhanced pain sensation.[2] This is true for patients in both surgical and medical ICUs.[3]

As high as 50% of patients have stated that their pain was inadequately treated in the ICU.[4,5] Inadequately treated pain results in serious clinical and psychological sequelae. It can lead to physiologic alterations, such as activation of catecholamines leading to vasoconstriction and increased myocardial oxygen demand as well as create metabolic disturbances, such as enhanced catabolic states altering glycemic control. Pain leads to inadequate coughing and deep breathing, predisposing patients to pneumonias and respiratory failure. In the short and long term, undertreated pain can lead to anxiety, lack of sleep, and posttraumatic stress disorder.[6]

ICU patients pose a unique challenge when it comes to recognition and quantification of pain. The barriers to effective pain management are numerous and from different sources. At the provider and nursing level, there is a knowledge gap in the physiologic effects of pain and the various types of medications that can be used, as well as a misconception that sedation is equivalent to analgesia. At the patient level, specifically for ICU patients, there is often an inability to report pain and a fear of being perceived as drug seeking.[6]

Numerous scales have been developed to standardize pain scores. For patients who are able to verbalize, the two primary pain scales are the numerical rating scale (NRS) and the verbal rating scale (VRS). The NRS asks patients to rate or circle a number between 0 and 10 or 0 and 100 that rates their pain, with 0 being "no pain" and the maximum number being the "worst pain they have ever experienced." The VRS asks patients to describe different levels of pain using adjectives such as *mild, moderate,* or *severe* pain.[7] Both scales have been shown to be comparable in quantifying acute pain.[8]

In patients who are unable to verbalize, there is the Wong-Baker FACES Pain Rating Scale, the Behavioral Pain Scale (BPS), and the Critical Care Pain Observation Tool (CPOT). The FACES pain scale allows the provider to determine a patient's level of pain based on a scale of facial expressions from smiling to grimacing. The BPS and CPOT scales quantify pain based on variables that have to do with compliance with the ventilator, movement/muscle tension of limbs, and facial expression to add up to a numeric score to quantify a pain level. Additionally, the use of vital sign parameters should also be considered, with tachycardia, hypertension, and tachypnea often being the most obvious signs of uncontrolled pain. Although these nonverbal behavioral scoring systems may be the only options for patients who are unable to communicate, they have several limitations, particularly in patients with dementia, cultural differences, or confounding factors that can influence any of the measured parameters. In head-to-head comparisons, self-reported pain scales have been felt more ideal than behavioral pain scores.[9]

Pain Control Medications—Opioids

Narcotic is a general term used to describe a class of drugs that produce sensory depression. Opioids are derived from the natural chemical opiate. Opioids bind to the three most recognized opioid receptors, the μ (now known as mu opioid [MOP]), δ (delta opioid [DOP]), and κ (kappa opioid [KOP]) receptors (however, up to 17 different classes of opioid receptors have been discovered). The physiologic effect of each opioid is determined by its pharmacodynamics in relation to each class of receptors.

Agonists to the MOP receptor cause analgesia and respiratory depression. Activation of MOP receptors in the midbrain activates descending inhibitory neurons and, through a series of effects, causes a reduction in the nociceptive transmission to the thalamus.[10] Agonists to the DOP receptor cause spinal analgesia and reduced gastric motility. Finally, agonists to the KOP receptor produce diuresis and dysphoria.[10] Through the same receptors, opiates produce a series of side effects, such as depressed consciousness and euphoria (leading to its addictive potential), respiratory depression, histamine release that can cause pruritus and reduction in systemic vascular resistance (SVR; hypotension), and gastrointestinal (GI) dysmotility resulting in constipation, nausea, and vomiting.

Morphine is the opioid that all other opioids are compared with. It can be given in an oral, intravenous, transdermal, or sublingual form. Morphine has low lipid solubility and slow penetration through the blood-brain barrier, making its onset of action relatively slow. In addition, half of orally ingested morphine will be metabolized through first-pass metabolism and will not reach the systemic circulation. In comparison, fentanyl and remifentanil are 600 times more lipid soluble than morphine and have a rapid onset of action with a lower risk of hypotension because they do not promote histamine release. Remifentanil offers the added benefit of being rapidly metabolized, as opposed to fentanyl, which gets stored in fat, making remifentanil the drug of choice in the operating room. Uniquely, tramadol, another opioid medication, acts on the MOP receptors and acts as a serotonin-norepinephrine reuptake inhibitor. Morphine-equivalent dosing of all commonly used opioids and their onset of action and half-lives are listed in Table 46.1.

Patients with a history of chronic narcotic use will not only build up a tolerance for opioids (a larger dose will be required to obtain the same effect), but it is now thought that they also experience opioid-induced hyperalgesia.[11] The mechanism for this

TABLE 46.1 Morphine Milligram Equivalents and Pharmacokinetics of Opioids

	ORAL MORPHINE	IV MORPHINE	CODEINE	IV FENTANYL	ORAL HYDROMORPHONE	OXYCODONE	TRAMADOL
Equivalent dosage (mg)	1 (Ref)	0.3	7	0.003	0.2	0.67	4
Onset of action (min)	20–30	5–10	30–60	0.5	15–30	10–15	60
Peak effect (hours)	1–1.5	0.3	1–1.5	0.08–0.25	0.5–1	0.5–1	2–3
Half-life (hours)	2–4	1.5–3	3	0.5–1	2-3	3–4	6

is likely multifactorial but involves altered opioid intracellular signaling and neuronal sensitization via glial toll-like receptor 4 (TLR4) signaling, among other pathways.[11] Many patients with a history of chronic opioid use or abuse will be on methadone or buprenorphine (buprenorphine in combination with naloxone is known as *Suboxone*). Methadone is a synthetic opioid agonist that is used to both curb withdrawal symptoms and control cravings. In the ICU, the goal for these patients is to provide adequate pain control and prevent withdrawal. This may often require a multidisciplinary approach.

In the acute setting, a patient's home methadone dose should be started as soon as possible, and additional analgesia may be given for acute pain management. Methadone dosage changes should only be done in conjunction with an addiction or substance abuse specialist.[11] Similarly, patients on buprenorphine maintenance therapy should continue their standard dose (without the naloxone component) with additional analgesic medications for the management of acute pain. Previously, there was a concern that buprenorphine, a potent partial MOP receptor agonist, may act as a competitor against full MOP receptor agonists, making any additional pain control difficult. However, multiple studies have shown similar morphine-equivalent opioid requirements with either methadone or buprenorphine maintenance therapy.[12,13]

For opioid overdose or concerns with respiratory depression, naloxone can be given. Naloxone is a nonselective opioid receptor antagonist, with its highest affinity being to the MOP receptor, becoming a competitive inhibitor. When given intravenously and intranasally, its effects can be seen within 2 minutes. Repeated doses may be necessary because the half-life of naloxone is shorter than the half-life of many opioids.

Pain Control Medications—Nonopioids

Multimodal pain therapy is essential for both adequate pain control and for its opioid-sparing effects. Ibuprofen and ketorolac are nonsteroidal antiinflammatory drugs (NSAIDs) that inhibit the activity of cyclooxygenase enzymes, which inhibits the synthesis of prostaglandins (important in inflammation) and thromboxanes (important in clotting). Ketorolac has been shown to reduce the use of opioids by up to 50%.[14] Ketorolac should only be used for up to 5 days, given the risk of bleeding and kidney injury in longer durations. In addition, the dose should be reduced in elderly patients or those with a lower body mass index.

Similar to NSAIDs, acetaminophen also inhibits cyclooxygenase, without the antiinflammatory effects, and also has effects centrally, with multiple proposed mechanisms of action.[15] Regardless, it provides extremely good pain control and is an important adjunct in multimodal pain protocols. Caution should be used in patients with liver disease or when using it in addition to other drug combinations that contain acetaminophen because overdose and toxicity can lead to severe hepatic failure.

Other adjuncts include long-acting local anesthetic regional blocks for injury patterns or surgical incisions with identifiable pain distributions. Blocks have been shown to reduce opioid requirements in the first 24 to 72 hours.[16-18] A downside is that these are temporary forms of pain control that will wear off with the half-life of the anesthetic used. However, an epidural catheter can provide a continuous infusion of local anesthetic, with or without an opioid, for continuous pain relief.

For neuropathic pain, drugs like gabapentin and pregabalin can be used. Both bind to a subunit of voltage-dependent calcium channels and act as an inhibitor. It is debated whether pregabalin has a higher affinity for the targeted ligand, but it is known to be at least two times more potent of an analgesic than gabapentin.

Agitation and Delirium

Agitation

Agitation is a "psychomotor disturbance characterized by an increase in both motor and psychological activities," often driven by anxiety, with disorganized actions and thoughts that can compromise a patient's care in the ICU.[19] To assess level of consciousness, there are several scoring systems. The Glasgow Coma Scale (GCS) provides a global assessment of a patient's level of consciousness, particularly after a brain injury. It has three components: ocular response, verbal response, and motor response. The score ranges from 3 to 15, with 3 being completely unresponsive and 15 being a normal level of responsiveness. In the ICU, the most commonly used method of assessing level of sedation and agitation is the Richmond Agitation-Sedation Scale (RASS).[20] This scale has been validated and demonstrated to have interrater reliability and consistency.[21]

The first steps for the treatment and prevention of agitation in the ICU should always be nonpharmacologic. These include providing frequent reassurance, prioritizing comfort, providing adequate pain control, encouraging family visitation, and prioritizing sleep when able.[19] Restraints can be used if a patient is harming themselves or others, but the decision to use restraints should be made with careful consideration and reassessed on a daily basis because of their potential for physical and psychological harm.

Sedation medications. Benzodiazepines bind to the gamma-aminobutyric acid-A (GABA-A) receptor to alter its configuration and increase the flow of GABA, an inhibitory neurotransmitter, causing sedation, anxiolysis, and muscle relaxation. Common uses are for alcohol withdrawal, anxiety disorders, seizures, and sedation in the ICU. Benzodiazepines are categorized into three groups: short acting (i.e., midazolam), intermediate acting (i.e., lorazepam), and long acting (i.e., diazepam). Midazolam and lorazepam are the primary benzodiazepines used for sedation in the ICU. Midazolam has high lipid solubility and therefore has rapid onset and rapid uptake by tissues, resulting in its short-acting nature. Given that it is rapidly stored in tissues, the use of midazolam infusions is typically limited to a short duration to avoid drug accumulation. The other downside of benzodiazepines is that they can promote delirium, particularly in the elderly. Given the concern for accumulation in tissues and delays in waking patients up after weaning sedation, the American College of Critical Care Medicine's (ACCM) Pain, Agitation and Delirium Clinical Practice Guidelines advise the use of nonbenzodiazepines for sedation in critically ill patients.[22] This recommendation was confirmed by studies showing decreased duration of mechanical ventilation and ICU length of stay with the use of nonbenzodiazepines for sedation.[23]

The most commonly used nonbenzodiazepine sedative in the ICU is propofol. Similarly, it acts as a potentiator of the GABA-A receptor, and at high doses, it may act as an agonist as well. Propofol does not have any analgesic effects. It can be given as boluses and often as an intravenous infusion for mechanically ventilated patients in the ICU. After discontinuing the medication, awakening occurs within 15 minutes. The adverse effects are significant respiratory depression (which is why its use is limited to monitored settings and/or mechanically ventilated patients) and systemic vasodilation leading to hypotension. Green urine may be noted from phenol metabolites. A relatively harmless side effect is the hypertriglyceridemia that can occur because of the lipid emulsion in propofol solutions. A more serious but rare side effect is propofol-related infusion syndrome (PRIS). The risk factors include high doses ($>$4 mg/kg/h) over a long duration ($>$48 hours). The syndrome is characterized by lactic acidosis, rhabdomyolysis, acute renal failure, and heart failure, with an overall mortality of up to 50%.[24] Treatment involves supportive management and discontinuing propofol.

Dexmedetomidine is an α_2-receptor agonist and produces cooperative sedation, meaning that patients have a certain level of arousal that allows them to interact but can return to their prior sedation state (similar to sleep/wake). Dexmedetomidine has sedative, amnestic, and some analgesic properties. It does not cause respiratory depression and can be used in patients who are not mechanically ventilated. Multiple randomized controlled trials have shown that sedation using dexmedetomidine was noninferior to sedation with midazolam or propofol and was associated with a shorter duration of mechanical ventilation.[25] Adverse effects, due to its potent α_2 effects, include hypotension and bradycardia, which are dose-dependent side effects. Similarly, clonidine is an oral or transdermal α_2-agonist and can be used to wean from benzodiazepines or dexmedetomidine.

Regardless of the pharmacologic agent, daily sedation holidays, defined as an interruption in sedative infusions until patients are awake, reduce the duration of mechanical ventilation and ICU length of stay. It is now standard of care for mechanically ventilated patients in the ICU to receive daily sedation holidays.

Delirium

Delirium is a disturbance in attention that is associated with impaired cognition that develops over a short period of time.[26] Up to 80% of mechanically ventilated patients develop delirium.[27] Delirium can present as hyperactive (restless, combative), hypoactive (lethargy, apathy), or mixed type (fluctuating between hyper- and hypoactive). The presence of delirium is associated with poor outcomes, including increased length of stay and higher mortality.[28] It can be difficult to identify patients suffering from early delirium, particularly those with hypoactive delirium. The Confusion Assessment Method for the Intensive Care Unit (CAM-ICU) is a commonly used, reliable, validated, and rapid instrument to assess for delirium.

There is limited high-quality evidence to suggest that any pharmacologic agent can prevent delirium. In multicenter, randomized controlled trials with placebo controls, antipsychotics, whether given prophylactically or for the treatment of delirium, failed to reduce the delirium rates or associated ICU mortality.[29,30] Dexmedetomidine has also been shown, compared with placebo, to decrease the incidence of delirium without a difference in any other clinical outcome measures.[31] Despite their common use, a 2018 Cochrane review showed that antipsychotics have no effect on delirium severity or mortality.[32] *The only conclusive preventative measure is nonpharmacologic therapies that include establishing a sleep/wake cycle and frequent reorientation.*

Delirium management is complex and involves a combination of pharmacologic and nonpharmacologic therapies. Nonpharmacologic mechanisms include treating any underlying medical conditions, managing pain, using sedation holidays, and providing frequent reorientation. Antipsychotic agents are often used to treat hyperactive delirium (i.e., agitation). Haloperidol, a first-generation (typical) antipsychotic, blocks dopamine receptors in the central nervous system. Adverse effects include extrapyramidal reactions, such as rigidity and spasmodic movements, and neuroleptic malignant syndrome with severe muscle rigidity and rhabdomyolysis. Atypical antipsychotics work through the same dopamine mechanism but are less likely to cause extrapyramidal symptoms.

CARDIOVASCULAR SYSTEM

The cardiovascular system is integral to the perfusion of all systemic organs. Cardiovascular dysfunction can be separated broadly into three categories: cardiac arrhythmias, cardiogenic shock, and myocardial ischemia. All of these areas are affected in the setting of primary cardiac dysfunction, such as heart failure or a myocardial infarction (MI), but they may also be affected by extracardiac disease processes. For example, pulmonary embolism (PE) can lead to right heart failure, hyperthyroidism can lead to arrhythmias, and increased metabolic demand can lead to cardiac ischemia. This section begins by briefly covering normal physiology, continues on to disorders encountered in these three areas and their treatments, and concludes with invasive and noninvasive methods of monitoring the heart and fluid status.

Cardiac Physiology

The heart is a two-pump circuit in sequence. All blood that goes out of the right ventricle to the pulmonary circulation must then be pumped out of the left ventricle to the system circulation, with important exceptions that arise in the setting of congenital cardiac anomalies and a minor exception from bronchial arteries and veins. There is a vast difference in resistance between the pulmonary vascular bed faced by the right heart and the systemic vascular bed faced by the left heart, with the pulmonary pressures and resistance being significantly lower. The heart's ultimate function is to supply oxygenated blood to the tissues of the human body. This is quantified by the oxygen delivery (DO_2) equation:

$$\begin{aligned}\text{Oxygen delivery} = {} & (\text{cardiac output [CO]})(\text{hemoglobin} \\ & \times 1.3 \times \text{oxygen saturation} + 0.003 \\ & \times \text{partial pressure of dissolved oxygen})\end{aligned}$$

In examining this equation, one observation is evident: the primacy of the hemoglobin and oxygen saturation in determining the carrying capacity of oxygen by the blood and the relatively trivial contribution of dissolved oxygen. CO is defined as the blood flow put out by the heart per unit time, typically expressed in liters per minute. In an average-sized adult, CO is 4 to 6 L/min. A common method of normalizing the CO is the use of cardiac index (CI), which is defined as the CO per unit total body surface area (TBSA).

Vascular resistance is the collective resistance of all vessels, including arteries and veins, against the flow of blood, and there are two such resistances: the SVR faced by the left ventricle and the pulmonary vascular resistance (PVR) faced by the right. The relationship between flow, pressure, and resistance is defined by Ohm's law:

$$V = IR$$

which can be translated to any portion of the cardiovascular circuit as follows:

$$\text{Pressure gradient} = (\text{flow})(\text{resistance})$$

For example, (MAP – CVP) = CO(SVR), where MAP = mean arterial pressure, and CVP = central venous pressure, but this can likewise be applied to the pulmonary circulation.

These relationships guide decisions about fluid and vasopressor therapy, which are discussed later. The lower PVR consequently requires a smaller right heart muscle volume (lower pulmonary artery pressure) to supply the lungs with the same CO as the rest of the body. This means that the right heart is unable to maintain its CO in the face of large, acute rises in PVR, and this lack of reserve has significant consequences in situations such as trauma pneumonectomy and acute PE. In both these situations, a sudden rise in PVR, particularly in the context of a low preload, can lead to cardiovascular collapse.

The myocardium is supplied primarily by the coronary arteries. During systole, the subendocardial vessels experience retrograde flow, and thus, the heart is primarily supplied during diastole. Additionally, the aortic valve leaflets cover the coronary ostia to an extent during normal systole and aortic flow. This has important implications for cardiopulmonary resuscitation because failure to allow for full recoil of the chest may reduce blood supply to the subendocardium during resuscitation.

The heart's rhythm is controlled by pacemaker cells. The primary node is the sinoatrial node, which is influenced by sympathetic stimulation from the sympathetic trunk, mainly arising from the T1 to T4 spinal levels, which stimulates positive chronotropy. Parasympathetic stimulation results in negative chronotropy and is mediated via the vagus nerve. The heart has a series of escape pacemakers, which are, in order, the atria, the atrioventricular (AV) node, and the ventricles themselves. As long as the sinoatrial node paces above the intrinsic rate of these escape pacemakers, and as long as those impulses are transmitted through the AV node and to the ventricles, impulses from the sinoatrial node control the heart rate.

Cardiac Arrhythmias

Supraventricular Tachycardias

Atrial fibrillation. Postoperative atrial fibrillation is common, occurring in 8% of major surgery and 45% of cardiac/thoracic operations. Recent work has noted that the risk of thromboembolism after the development of atrial fibrillation after noncardiac surgery is similar to that of patients with nonvalvular atrial fibrillation. However, although the 2016 European Society of Cardiology guidelines now recommend anticoagulation for postoperative atrial fibrillation after cardiac surgery, they do not address other major surgical procedures. In general, if the rhythm persists for >48 hours after surgery, consideration should be given to initiate anticoagulation based on CHA_2DS_2VASc score, as with other, nonoperative patients, provided the surgical bleeding risk is acceptable.

For atrial fibrillation with rapid ventricular response, acute management is dependent on the hemodynamic stability of the patient. If the patient is acutely unstable, immediate synchronized electrocardioversion is mandated, as it is for any tachyarrhythmia causing acute instability. In the context of hemodynamic stability, pharmacologic methods should be employed, including amiodarone, β-blockers, and calcium channel blockers. Amiodarone is favored in the context of heart failure because calcium channel blockers are contraindicated in heart failure. That said, a recent retrospective review documented that metoprolol had the greatest success in the treatment of acute atrial fibrillation, defined by rate control without the need for a second agent. Other studies have noted more rapid rate control (without cardioversion) of atrial fibrillation with diltiazem in both the emergency department and the ICU but also noted an increased rate of hypotension with its use relative to amiodarone. Acutely, digoxin alone is not recommended owing to its slow onset and comparative lower success in controlling atrial fibrillation, although this is sometimes used in conjunction with the aforementioned agents and in the long term in the setting of refractory atrial fibrillation.

Two points of caution should be noted. Traditionally, it was held that cardioversion of an atrial rhythm into a sinus rhythm could safely occur up to 48 hours after initiation of the rhythm. Thereafter, either a transesophageal echocardiogram to verify lack of clot formation in the left atrium or 4 weeks of anticoagulation was recommended before cardioversion if done after the initial 48 hours, except in cases of acute hemodynamic compromise. However, recent work suggests that the safe period of cardioversion may be much shorter, as little as 12 hours. Although all drugs used to treat atrial fibrillation may induce cardioversion into sinus rhythm, amiodarone is especially prone to do so. Thus, it should be used with caution in patients with longer time periods of atrial fibrillation because of its higher tendency to result in a return to sinus rhythm. Second, in patients with an accessory pathway, such as Wolf-Parkinson-White syndrome, atrial fibrillation with preexcitation may develop. The use of calcium channel blockers, β-blockers, amiodarone, and digoxin is contraindicated in such instances because of the risk that after suppression of the AV node, the accessory pathway will result in an exacerbated tachycardia. In this scenario, ibutilide or procainamide is recommended by the most recent guidelines.

In summary, if the patient is hemodynamically stable, carefully review 12-lead electrocardiograms (ECGs) (both those taken during the acute episode and historical comparisons, if available) to confirm the rhythm and rule out an accessory pathway, and make aggressive attempts at prompt chemical cardioversion using β-blockade and/or amiodarone. If the rhythm persists, a transition to a rate control strategy with β-blockers or calcium channel blockers and consideration of anticoagulation may be warranted.

Multifocal atrial tachycardia. Multifocal atrial tachycardia is most commonly associated with hypomagnesemia. Pulmonary insufficiency, hypokalemia, and coronary artery disease are other known precipitating factors. An empiric push of 6 mg of IV magnesium sulfate often terminates multifocal atrial tachycardia. If correcting hypomagnesemia and hypokalemia (in that order) is not effective, then β-blockers and calcium channel blockers should be tried.

Atrial flutter. Atrial flutter is commonly caused by the same disorders that give rise to atrial fibrillation. It is also not infrequent after the treatment of atrial fibrillation with amiodarone. It is an unstable rhythm and has the potential to spontaneously degenerate into atrial fibrillation or revert to normal sinus rhythm, particularly if the underlying factors have been addressed. The management of atrial flutter is similar to that of atrial fibrillation, with rate- and rhythm-control options, but electrocardioversion is the preferred therapy. Antiarrhythmic drug therapy is also an option and may be selected for stable patients who are too high risk to undergo the sedation that would typically be required before electrocardioversion. Additionally, ibutilide is FDA approved for the conversion of atrial flutter to normal sinus rhythm and has shown superiority to amiodarone and procainamide in this setting. It should be remembered that all antiarrhythmic drugs have proarrhythmic tendencies, and ibutilide is no exception, with a significant risk of torsades de pointes. It must be used with caution in patients at high risk for torsades de pointes, and patients should be in a monitored setting after its use. IV magnesium given alongside ibutilide will enhance its ability to break atrial flutter and prevent torsades de pointes.

Atrioventricular nodal reentrant tachycardia. There are numerous other subtypes of supraventricular tachycardias, of which the most common is AV nodal reentrant tachycardia. The pathophysiology is a reentrant circuit. Although it is sometimes difficult to distinguish from sinus tachycardia and ventricular tachycardia, blocking the AV node by using vagal maneuvers can reveal the underlying rhythm. Agents acting at the AV node (adenosine, β-blockers, and calcium channel blockers) are all options to terminate these rhythms. It is important to distinguish a paroxysmal supraventricular tachycardia with a block from a ventricular tachycardia because both may present with a widened QRS. A history of heart disease or operation portends a ventricular tachycardia. Furthermore, adenosine will aid in distinguishing the rhythms because it will stop a supraventricular tachycardia but not a ventricular tachycardia. Additionally, ventricular tachycardia will not respond to β-blockers or calcium channel blockers.

Ventricular Tachycardia

Monomorphic ventricular tachycardia. Ventricular arrhythmias are rare in young patients and those without a history of heart disease. Options for treatment in stable patients include lidocaine, amiodarone, and procainamide; these are also adjuncts to consider if initial defibrillation for stable or unstable patients fails to convert a ventricular tachycardia into a sinus rhythm. Additionally, a recent study demonstrated the superiority of procainamide to amiodarone in the conversion of stable ventricular tachycardia. Because procainamide is a therapeutic option for atrial fibrillation with rapid ventricular response, supraventricular tachycardias, and ventricular tachycardias, it may be a reasonable option if one is uncertain of the rhythm. Although some patients with ventricular tachycardia may appear stable, they are at high risk for sudden deterioration and must be monitored closely and treated expeditiously.

Polymorphic ventricular tachycardia. Fundamentally, a monomorphic ventricular tachycardia indicates that ectopic beats are arising from one, often ischemic, focus in the ventricles, typically secondary to coronary artery disease. Polymorphic ventricular tachycardia indicates either multiple foci of ectopic beats or, more commonly, global dysfunction. The latter is a rhythm classically known as *torsades de pointes,* a feared rhythm for which a predisposing factor is a prolonged QT interval. This can be caused by a variety of drugs and with or without an inherited prolonged QT interval. It is imperative to note that many antiarrhythmics, including procainamide, lidocaine, and ibutilide, prolong the QT interval, as do commonly used antipsychotic drugs such as haloperidol and antiemetics such as ondansetron. The treatment is focused on aggressive administration of magnesium and unsynchronized cardioversion if unstable.

Bradycardia

Similar to the tachyarrhythmias, management of bradycardia can be broken down into pharmacologic and electrical support. In some cases, bradycardia may be physiologic or the patient's baseline (e.g., many young trauma patients). If the bradycardia is not causing any hemodynamic compromise, it may not be necessary to treat. However, sudden acute and symptomatic bradycardia may be indicative of severe underlying pathology, including acute spinal cord injury, MI, hypoxia, and various toxicologic states, as well as global dysfunction from severe sepsis. In general ICU populations, bradycardia can be a sign of profound cardiac dysfunction. Acute management includes atropine, epinephrine, and pacing; however, these are temporary supports (apart from spinal cord injury), and the priority must be reversal of the underlying cause.

Sinus bradycardia. Sinus bradycardia may be a normal resting rhythm for many fit, young individuals, and no treatment is required. However, context is important because it may also be seen in profound shock states as a peri-arrest rhythm. Most cases of hemodynamically stable sinus bradycardia can be treated with atropine. Sinus bradycardia secondary to a spinal cord injury can occur in high (cervical) spinal cord injuries and should be treated with atropine and concomitant vasopressor therapy to treat neurogenic shock as required (an agent with additional chronotropic effects should be considered). Similarly, sinus bradycardia associated with MI, commonly seen in inferior wall infarctions as a result of involvement of the sinoatrial node, can be treated with atropine as well.

Sinus bradycardia secondary to the use of dexmedetomidine, increasingly used for sedation and anxiolysis in the ICU, requires a different mindset. If this occurs, treatment of the resultant hypotension with vasopressors is required until the drug wears off, and/or pacing may be required if the hypotension is significant and unresponsive to moderate vasopressor use. Atropine and epinephrine will be ineffective with this etiology because of the α_1-antagonist effect of dexmedetomidine.

Heart block, junctional or ventricular bradycardia. Junctional or ventricular bradycardia is a result of profound AV node dysfunction. There is no apparent atrial activity. Treatment with temporary pacing may be required if the CO falls. Atropine is not effective in this scenario because it acts on the dysfunctional AV node.

Relatedly, AV conduction blocks may result in bradycardia.[33] In a first-degree block, there is simply a delay in conduction between atria and ventricles, with a PR interval >0.2 s. In a second-degree block, beats are intermittently not conducted through the AV node. In a second-degree Mobitz I ("Wenckebach") block, there is a progressive lengthening of the PR interval until a ventricular beat is eventually dropped. The cycle then starts again. In a Mobitz II block, the PR interval is constant, but intermittent beats are dropped. In a third-degree or "complete" heart block, there is no relationship between atrial and ventricular rhythms. First-degree blocks generally do not require treatment, third-degree blocks will often require pacing, and indications for pacing in second-degree blocks are dependent on context and hemodynamic stability.

Shock

The most severe hemodynamic alteration is shock, which is a condition of circulatory failure resulting in end-organ dysfunction secondary to reduced perfusion. A shock state itself is indicated by signs of end-organ dysfunction, such as rising lactate, altered mental status, falling urine output, and liver enzyme elevation. Each form of shock demands different responses, and when different forms of shock are combined, the appropriate diagnosis and management can be challenging. Shock is classified broadly into four categories: distributive, hypovolemic, cardiogenic, and obstructive.

Distributive Shock

Neurogenic shock. Neurogenic shock occurs secondary to the loss of sympathetic tone after a spinal cord injury. The overall etiology is decreased vascular resistance; however, there are two variants based on the location of the spinal cord injury. In lower spinal cord injuries below C5, the hypotension causes an appropriate reflex tachycardia. In higher spinal cord injuries at C5 and above, the patient is often bradycardic because the heart does not respond appropriately to the increased vagal tone due to the lack of sympathetic innervation to the heart. Neurogenic shock generally results in a "warm" shock because peripheral vasculature remains dilated. Treatment consists of vasopressor support to maintain blood pressure. Although phenylephrine was previously considered the first-line pressor in neurogenic shock for the sake of peripheral vasoconstriction, norepinephrine is increasingly used, particularly in bradycardic patients.

Of note, neurogenic shock does not equate to spinal shock. Spinal shock is *not* a hemodynamic phenomenon; rather, it results in the temporary loss of reflexes after a spinal cord injury, most commonly the bulbocavernosus and cremasteric reflexes. Although these phenomena may co-present in the setting of spinal cord injury, they are to be distinguished.

Septic shock. Septic shock is one of the most common types of shock encountered in the surgical ICU and consists of a dysregulated immune response arising from inflammatory mediators released by the body in response to bacterial or fungal pathogens. In the past, sepsis was defined as a systemic inflammatory response syndrome (SIRS) accompanied by a suspected source of infection, with SIRS being defined as derangements in two or more of four parameters: white blood cell count, temperature, heart rate, and respiratory rate. Also previously, septic shock was then sepsis unresponsive to fluid resuscitation, requiring vasopressor support to maintain the blood pressure. These definitions are now considered outdated, and they have been superseded by new guidelines that base the definition of sepsis and septic shock on sequential organ failure assessment (SOFA) scores. Specifically, organ dysfunction represented by an increase in SOFA score of 2 or more represents sepsis, whereas sepsis with hypotension despite fluid resuscitation and/or a serum lactate greater than 2 despite a lack of hypovolemia represents septic shock.[34] A "quick SOFA" or "qSOFA" consists of respiratory rate, altered mentation, and low systolic blood pressure and may be used similarly, although it should be noted that the most recent Surviving Sepsis Campaign guidelines recommend against using qSOFA over SIRS or other previous criteria.[35]

Previous sepsis management guidelines included immediate lactate measurement (and other laboratory values), an empiric 2-L fluid bolus, empiric antibiotic administration after cultures being drawn, appropriate measurement and titration of fluid resuscitation to CVP and central venous oxygen saturation, and potentially a Swan-Ganz catheter to accurately capture hemodynamic variables. This was known as an *early goal-directed therapy* (EGDT).[36] Subsequent randomized controlled trials suggest little benefit to this type of "bundle"; however, some feel that the control groups were flawed in that much of EGDT has become the standard of care. If anything, these studies showed that attempting to correct every hemodynamic metric may result in overresuscitation. Currently, the underlying principles of EGDT—metric-guided hemodynamic resuscitation to goal euvolemia—are still very much accepted; what has changed are the hemodynamic measures of volume status.

What is widely accepted is that early recognition and administration of antibiotics lead to increased survival, although this must be balanced against the risk of increasing antibiotic resistance and the harms associated with administering antibiotics to patients who do not require them. Early source control of the infection is also positively associated with outcomes.

Regarding treatment, it is important to realize that the underlying pathophysiology consists of both vasodilation and leakage of fluid into the interstitial spaces resulting from an increase in vascular permeability. Consequently, increasing vasoconstriction alone will not by itself reverse the shock state. Traditionally, fluid resuscitation followed by vasopressor therapy only when fluids no longer produce an increase in blood pressure (fluid responsiveness) has been standard.

The most recent updated guidelines for the overall management of sepsis were released by the Surviving Sepsis Campaign in 2021.[35] They continue to recommend crystalloid fluid resuscitation in the form of 30 cc/kg in the first 3 hours. Less controversially, the guidelines recommend continued close monitoring, a target MAP of 65 mm Hg, and the use of lactate as a measure of tissue hypoperfusion and as a guide to resuscitation.[37] The use of CVP to guide fluid resuscitation has been largely discredited, owing to its inability to reliably predict fluid responsiveness. In its place, the guidelines recommend the use of dynamic parameters, including passive leg raise, fluid challenges, pulse pressure variation in response to mechanical ventilation, and other techniques. Many devices and techniques exist to predict fluid responsiveness, but ultimately, clinical judgment must still be used to interpret the end points of resuscitation and guide fluid resuscitation and vasopressor therapy in septic shock states.

Currently, when crystalloid fluid resuscitation is not effective at raising blood pressure, the vasopressor of choice is norepinephrine, which has been shown to be superior to the other vasopressors. Epinephrine can be substituted if norepinephrine is inadequate, particularly if a cardiogenic component of shock is suspected; however, it may lead to falsely elevated lactate concentrations and difficulty in using this as an end point for resuscitation. Phenylephrine should not be considered a first-line agent because it has been associated with higher in-hospital mortality in septic shock.

When norepinephrine requirements increase significantly (past a value of approximately 5 mcg/min), low-dose vasopressin should be added. This is based on research suggesting a relative vasopressin deficiency in inflammatory vasodilatory shock. The dose is 0.04 units/min and may decrease norepinephrine requirements to maintain the blood pressure. High-dose vasopressin is not recommended. When high doses of norepinephrine and added vasopressin are insufficient, epinephrine may then be added, with no data suggesting a clear benefit. Dobutamine may also be used to augment tissue perfusion if the CO is low.

The use of corticosteroids in septic shock has been controversial for over three decades. The current recommendation by the Surviving Sepsis Campaign is for low-dose steroids in vasopressor-dependent, volume-replete septic shock. There have been several studies investigating the use of glucocorticoids in septic shock, with mixed results. For example, the Adjunctive Glucocorticoid Therapy in Patients with Septic Shock (ADRENAL) study did not demonstrate decreased 90-day mortality, but it did demonstrate faster resolution of shock and shorter initial duration of mechanical ventilation.[38]

Other etiologies of distributive shock. Other etiologies of distributive shock include anaphylactic and endocrine shock. The former occurs in response to an allergic stimulus, with the first-line treatment being epinephrine. Optionally, adjuncts such as diphenhydramine and steroids may be used. It should be noted that diphenhydramine does not manage airway symptoms and may cause hypotension, and steroids take several hours to be effective and have never been proven to be of benefit.

Endocrine shock results from severe myxedema coma from hypothyroidism and Addisonian crisis from acquired or iatrogenic hypothalamic-pituitary-adrenal axis suppression. The diagnosis depends on an accurate history and physical examination in both cases. Often, until laboratory tests rule out coexisting Addison disease, the treatment for myxedema coma includes empiric steroids alongside levothyroxine and liothyronine.

Hypovolemic Shock

Hypovolemic shock is characterized by increased SVR and decreased CO, with the latter being secondary to decreased preload. This is a so-called "cold shock," with cold extremities secondary to vasoconstriction. For hypovolemic shock from dehydration or fluid losses, the treatment is relatively straightforward and includes fluid resuscitation with crystalloid.

Hemorrhagic Shock

In hemorrhagic shock, blood products are the resuscitative fluid of choice. Crystalloid administration leads to anemia and coagulopathy. Broadly speaking, two resuscitation strategies are possible: empiric resuscitation, often with a so-called "massive transfusion protocol" (MTP),[39] or resuscitation based on analysis of clotting via thromboelastography (TEG) or rotational thromboelastometry (ROTEM). If empiric transfusion is to be pursued, this can be done with either component therapy or using whole blood. The first strategy, administration of blood products in an empiric ratio, is commonly employed in many centers as part of an MTP to be administered until control of bleeding can be obtained and/or resuscitation end points have been met. Alongside this are adjuncts such as the administration of tranexamic acid (TXA).[40] If component therapy is used, a 1:1:1 ratio of plasma (i.e., fresh frozen plasma [FFP]) to packed red blood cells (pRBCs) to platelets should be used. Recent data suggest that, if available, whole blood may be superior to component therapy in hemorrhagic shock.[41]

Although empiric whole blood and/or component therapy is certainly a reasonable approach, if available, viscoelastic testing (TEG or ROTEM) may be beneficial. These are dynamic tests of clotting ability and strength—for example, TEG uses vibration of a blood sample at a fixed frequency, with a light detector to measure meniscus motion. The impedance of the clot is displayed graphically over time, providing guidance as to which components or adjuncts (i.e., FFP, cryoprecipitate, platelets, or TXA) may be helpful.

There is some evidence for the use of TEG to augment empiric MTPs in trauma. In general, it seems that outcomes are equivalent *until* the amount of resuscitation surpasses a certain threshold. In a study from 2013, outcomes were generally similar, but there was a mortality benefit to TEG versus empiric MTP (33.3% vs. 54.1%) in patients with a penetrating mechanism who received more than 10 units of pRBCs.[42] This suggests that, at a minimum, once transfusion requirements surpass some threshold, TEG may be helpful. This has resulted in an Eastern Association for the Surgery of Trauma (EAST) practice management guideline endorsing TEG in trauma, surgical patients, and ICU patients.[43]

Although there is minimal evidence for the use of early vasopressors in hemorrhagic shock,[44] few would disagree that this may be a necessary temporizing adjunct as blood products are administered. Furthermore, there is specific evidence for a "vasopressin-deficient" state in which vasopressin administration may be helpful.[45]

Cardiogenic Shock

Cardiogenic shock is a "cold" shock in that it is characterized by decreased CO because of intrinsic "pump failure" or cardiac heart dysfunction, with compensatory vasoconstriction. Numerous causes for heart failure resulting in cardiogenic shock exist, but the most commonly seen is the acute or long-term sequelae of coronary artery disease. This shock state has multiple variants, including diastolic versus systolic failure and left heart versus right heart failure. Valvular obstruction may also be a cause of dysfunction. Heart failure progresses through three stages. Initially, the filling pressure of the ventricle increases, but contractility is preserved at the expense of increased pressure and congestion in the lungs. Next, the stroke volume begins to fall, but an increase in heart rate preserves CO. Finally, CO begins to fall.

Right heart failure. The mainstay of right heart failure therapy is straightforward. This includes fluid boluses until clinical euvolemia is achieved, followed by inodilator therapy with dobutamine or milrinone. This being said, fluid therapy must be used judiciously because dilation of the right ventricle may cause the septum to bow out into the left ventricle, resulting in decreased left ventricular function through interventricular interdependence. Inodilators both dilate the vasculature, reducing blood pressure, and promote CO by increasing contractility. They are ideal choices when the CO is low and the SVR high, but they often are not options if systemic blood pressure is low. For this reason, inodilators in conjunction with vasopressors such as norepinephrine are a commonly pursued strategy, with the inodilator titrated to the CO and the vasopressor titrated to an appropriate systemic blood pressure. Likewise, management of systemic hypotension accompanied by right heart failure should avoid vasopressors that increase the PVR (e.g., phenylephrine) and should instead favor those that do not (e.g., vasopressin, receptors for which do not exist in the pulmonary vasculature).

Left heart failure. It is imperative to determine the patient's fluid status when managing left heart failure. Although diuretics historically have been given to almost all patients in left heart failure on the basis of the theory that such patients are past the inflection point on the Starling curve, in reality, patients who are in cardiogenic shock may be fluid overloaded, hypovolemic, or euvolemic. Determination of fluid status may be deceptively difficult. Measures to determine volume status should include weight, pedal edema, and inferior vena cava ultrasound. Newer noninvasive monitoring tools that employ proprietary arterial waveform analysis may be helpful in management of hemodynamically deranged patients, although their accuracy may be limited to specific conditions.[46]

Similarly, the heart failure patient may be hypertensive, normotensive, or hypotensive. If the patient is hypertensive, then nitroglycerin, nitroprusside, or nicardipine may be used. All three will decrease the afterload, allow for the forward flow of blood to peripheral tissues, reduce the myocardial oxygen demand, and protect the heart from ischemic damage. Nitroprusside has the risks of worsening coronary ischemia and causing cyanide toxicity, so it is less preferred compared with the other agents. If the blood pressure is normal in a state of cardiogenic shock, inodilators may be used. Vasodilators can also be used with caution as long as the blood pressure is maintained. Finally, if both the blood pressure and CO are low, epinephrine or dopamine infusions may be tried; however, because of their peripheral vasoconstriction, they can further increase the afterload and worsen the patient's condition. This state has an extremely high mortality, and if it is refractory to pharmacologic measures, mechanical circulatory support may be warranted. These options include intraaortic balloon pumps, left ventricular assist devices, and venoarterial (VA) extracorporeal membrane oxygenation (ECMO). If a facility does not have these resources in-house, the patient should be considered for transfer to a center with these capabilities, possibly by having a mobile unit from the accepting facility arrive at bedside and placing the patient on mechanical circulatory support before transfer.

Obstructive Shock

The etiologies of obstructive shock include tension pneumothorax, cardiac tamponade, constrictive pericarditis, and massive PE. In all cases, the treatment is interventional in that it requires removal of the cause of the obstructive shock. Options include a needle decompression or thoracostomy tube in the case of pneumothorax; pericardiocentesis, pericardial window, or thoracotomy/sternotomy in the case of tamponade; and heparinization and systemic or catheter-directed thrombolysis with or without thrombectomy in the case of PE. A high index of suspicion is required in making these diagnoses.

Myocardial Infarction

Both myocardial ischemia and MI are feared entities in the perioperative period, both of them portending significant morbidity and mortality. The lack of ischemic symptoms or ECG changes associated with a rise in troponins is not a sign of safety; mortality remains high. Two fundamental types of MI exist. Type 1 MI is based on atherosclerotic plaque rupture and consequent ischemia and infarction of muscle that was being supplied by that blood vessel. In contrast, type 2 MI is based on a mismatch of the supply of blood and the heart's demand for it and is also commonly referred to as *demand ischemia*. The treatments for each type of MI flow naturally from their causes: revascularization for type 1 MI and reduction of cardiac oxygen demand for type 2 MI.

Type 1 MIs can be broken down into ST-elevation MI (STEMI) and non-STEMI (NSTEMI). As its name indicates, a STEMI classically involves symptoms and elevations in cardiac enzymes as well as evidence of ST elevations on ECG, whereas an NSTEMI is similar but without ECG evidence of infarction. Unstable angina is a symptom of ischemia but without cardiac biomarker elevation indicating injury. All three together form part of the spectrum of acute coronary syndrome.

The treatment of a type 1 MI in the postoperative period focuses on a percutaneous coronary intervention, with thrombolysis as an option if timely percutaneous coronary intervention is unavailable. In NSTEMI, intervention can be delayed in some cases for up to 72 hours. However, the overall intervention decision is complicated by the added burden of deciding on the risks and benefits of full-dose systemic anticoagulation in postoperative patients. In certain populations, such as those who recently underwent neurosurgical procedures, the risks of stroke or death from hemorrhage make percutaneous coronary intervention with its attendant anticoagulation unacceptable, whereas in other patients, the risks can be accepted.

In addition to the primary intervention, the complications of an acute MI must be managed. Cardiogenic shock should be managed as previously discussed. Nitroglycerin, either sublingual or IV, can be given for hypertension and chest pain. The distinction between a right- and left-sided MI is critical because giving nitroglycerin to reduce the afterload and myocardial oxygen demand in the setting of presumed left-sided MI may reduce the preload, resulting in right-sided heart failure if in fact the patient is suffering a right-sided MI. This could have catastrophic consequences. Pain control with any IV opiate, such as morphine, can be used to control chest pain symptoms if not relieved by nitroglycerin. The patient should be given aspirin and additional anticoagulant medications as specified by local protocol and depending on the course of therapy chosen. β-blockers should be initiated if there are no signs of cardiogenic shock because these are cardioprotective. However, if the patient is hypotensive or has a decreased ejection fraction or bradycardia, these should be avoided. Above all else, a defibrillator should be immediately available for the case in which the patient degenerates into a life-threatening unstable arrhythmia.

RESPIRATORY SYSTEM

A common manifestation of critical illness is respiratory failure requiring mechanical ventilation. Acute respiratory failure is caused by an inflammatory response resulting in alveolar collapse and interstitial edema, both resulting in hypoxia. The mainstay of treatment is supportive while minimizing the complications of positive pressure ventilation itself. Mastery of both airway management and mechanical ventilation is fundamental to the practice of critical care medicine.

Respiratory Physiology

Respiratory physiology is characterized by two linked processes: oxygenation and ventilation. *Oxygenation* refers to the addition of oxygen (O_2) to the bloodstream from inspired air. The fraction of inspired oxygen (FiO_2) of room air is typically 21%. Ventilation is the clearance of carbon dioxide (CO_2) generated by cellular respiration from the bloodstream. Although it is easiest to conceptualize these processes as entirely separate, they are clearly interrelated.

Both processes rely on air coming down the oral cavity, into the trachea, through the bronchi, and into the lung parenchyma (ventilation), where blood from the pulmonary arteries and arterioles flows to meet it (perfusion) at the alveolar-capillary interface. Ventilation is commonly referred to as *V*, whereas perfusion is commonly referred to as *Q*, such that an imbalance of ventilation and perfusion is referred to as *V/Q mismatch*. At the extremes of V/Q mismatch are shunt physiology, in which there is perfusion without ventilation, and dead space physiology, in which there is ventilation without perfusion. Some amount of both of these is normal: Less than 10% of total CO does not participate in gas exchange, and 20% to 30% of total ventilation does not equilibrate with blood. Increases in shunt fraction occur secondary to asthma, distention of alveoli from pulmonary edema or pneumonia, atelectasis, or PE, where excessive CO flows through nonembolized regions. Dead space ventilation takes place when the alveolar-capillary interface is destroyed by emphysema, when the CO is low, or when air overdistends the alveoli during positive pressure ventilation. It should be noted that there is some amount of "physiologic dead space"—that is, parts of the respiratory tract that do not participate in air exchange, including the trachea and bronchi.

Oxygen Therapy

Although supplemental oxygen via nasal cannula (NC) is commonplace in the ICU, it must be emphasized that oxygen itself is a drug, with risks and benefits, and should be used only when indicated. In intubated and mechanically ventilated patients, a target FiO_2 should be less than 50% if tolerated because this setting appears to be safe and without risks of pulmonary toxicities. Although theoretically, the FiO_2 could be dropped to 21% if tolerated, this is not commonly done, with extubation often taking place at an FiO_2 of 30% to 40% (and transitioning to another mode of supplementary oxygen delivery).

Noninvasive Ventilation

Some patients in impending respiratory failure may avoid intubation with noninvasive ventilatory support via continuous or bilevel positive airway pressure (CPAP or BIPAP). As the names suggest, CPAP involves the continuous delivery of a single set level of pressure, whereas BIPAP is set to different pressures for inspiration (IPAP) and exhalation (EPAP). Both CPAP and BIPAP provide positive end-expiratory pressure (PEEP), helping to keep the alveoli open at the end of expiration; BIPAP also adds extra pressure above and beyond the PEEP. Both CPAP and BIPAP are often worn at night by many patients with sleep apnea at home and should be provided to such patients in the hospital if indicated. BIPAP in particular has been shown to significantly benefit patients with pulmonary edema from a congestive heart failure exacerbation and is well suited to providing support over CPAP in cases of hypercarbic ventilatory insufficiency.

It is important to remember the contraindications of such devices, including altered mental status and consequent inability to protect the airway. Both machines involve a mask worn over the face, and any large-volume emesis event can rapidly turn into a large-volume aspiration and cardiac arrest event. Furthermore, the use of these modalities in patients with fresh esophageal, gastric, or duodenal anastomoses is relatively contraindicated because the positive pressure can increase upper GI insufflation. Although the normal resting pressure of the lower esophageal sphincter is greater than 10 mm Hg and noninvasive positive pressure ventilation (NIPPV; including CPAP and BIPAP) would often not exceed this pressure, many conditions and patient characteristics can reduce this protective mechanism and make the use of NIPPV a riskier proposition.

High-Flow Nasal Cannula

High-flow nasal cannula (HFNC) is another noninvasive mode of ventilatory support, by which oxygen is delivered at considerably higher flow rates than is achievable by regular NC. Whereas regular NC can deliver a maximum of about 10 L/min, HFNC can deliver oxygen up to 100% FiO_2 via up to 60 L/min of flow. Although there is some thought that HFNC may provide "some" positive pressure, this seems mechanistically unlikely, and the benefit seems more likely to simply be due to the more rapid delivery of oxygen. A 2015 study randomized hypoxic patients to HFNC, NC, or NIPPV and found no difference in intubation rates, but it did find favorable results for HFNC with regard to 90-day mortality.[47] There may also be some benefit to HFNC after extubation; a randomized trial in 2016 demonstrated a lower rate of 72-hour reintubation with HFNC versus conventional NC.[48]

Intubation and Mechanical Ventilation

Broadly, the indications for intubation are (1) airway protection, (2) hypoxia, and (3) hypercarbia. "Airway protection" can be required for a variety of reasons. One is depressed mental status, which is often taught with the mnemonic "GCS less than 8, intubate." However, this practice is not based on evidence and has been questioned in recent years.[49] Alternatively, impending loss of airway patency can be caused by edema secondary to hereditary angioedema, trauma, severe allergic reactions, or airway burns.

Hypoxia may be a result of pneumonia, pulmonary contusion, severe pulmonary edema, or acute respiratory distress syndrome (ARDS), among other causes. Hypercarbia and hypoventilation may be a result of respiratory depression secondary to opioids or other sedating medications, exhaustion and subsequent inadequate respiratory effort in the setting of increased work of breathing, or spinal cord injury, among others. Patients with a high spinal cord injury (above C5) may have a delayed presentation of ventilatory failure because there may be initial compensation by accessory muscles.

Intubation and the induction medications required to perform it are not without risk. Particularly in the patient who is already hemodynamically unstable, intubation can trigger hemodynamic collapse. The causes are multifactorial, including hemodynamic shifts induced by induction agents, temporary hypoxia during the procedure itself, and the influence of positive pressure ventilation on venous return to the heart. It is essential to resuscitate patients adequately before intubation and to use adjuncts such as vasopressors before and during intubation if indicated.

Standard Modes of Mechanical Ventilation

There are essentially four basic parameters that may be set in any ventilator mode. The first is some measure of "how big" a breath to give. In a volume-controlled mode, this would be a tidal volume; in a pressure-controlled mode, this would be an inspiratory pressure. The second is some measure of "how often" to give a breath. In a completely controlled mode, this is a respiratory rate; in other modes of partial support, this may be only intermittently controlled, with the patient triggering some to all of their own breaths. Third is PEEP. There may be some variation in how this is referred to and used, particularly in more advanced modes like "bilevel" or airway pressure release ventilation (APRV), but there will nearly always be some amount of positive pressure present in the circuit. Finally, the ICU provider can modulate the amount of oxygen in the delivered breaths by setting the FiO_2. Next, we will discuss in more detail some of the more common ventilator modes.

Assist Control

Assist control (AC) is one of the most commonly used modes of mechanical ventilation. AC can be achieved by setting either a tidal volume ("volume control," VC) or inspiratory pressure ("pressure control," PC). The former is more common. The other three parameters are set as described earlier. If the patient is not breathing spontaneously, the set respiratory rate is exactly what the patient will receive. If the patient triggers their own breaths, they will receive a "full" breath as set each time.

The choice of VC or PC is often dependent on which variable the clinician wants to control more. As stated, VC is more common because we generally desire control over the patient's minute ventilation (i.e., tidal volume multiplied by the respiratory rate) to ensure adequate CO_2 clearance. However, in the case of very poor compliance, it may be desirable to control the pressure to guard against barotrauma. With either mode, the so-called "free" variable (i.e., the peak and plateau pressures while in VC and the tidal volumes when in PC) must be carefully monitored.

Peak pressure, as measured by the ventilator, is the sum of the dynamic airway pressure (flow × resistance) and the alveolar pressure. For the most part, the component of concern is the alveolar pressure because this is where there is potential for barotrauma. When faced with elevated peak airway pressures, the first step is to rule out causes of increased airway resistance, such as a kinked tube or auto-PEEP from breath stacking, as well as other causes, such as tension pneumothorax or asthma. The airway component of this equation can be removed from the question by measuring a plateau pressure using an "inspiratory hold" or pausing the ventilator at the end of inspiration. With no flow through the airways, that term of the equation goes to zero, and the alveolar pressure is isolated. A high plateau pressure is a better reflection of the pressure seen by the alveoli and lung compliance. Keeping the plateau pressure below 30 cm H_2O is felt to be lung protective.

Pressure Support Ventilation

Another fundamental mode of mechanical ventilation is pressure support ventilation (PSV). It is directly analogous to a BIPAP machine. Every breath the patient takes is supported by a set pressure support with additional PEEP that is constant throughout the respiratory cycle. There are no mandatory breaths; every breath is triggered by the patient. This mode is an excellent tool to wean the patient from mechanical ventilation and is discussed further under extubation.

Synchronized Intermittent Mandatory Ventilation

Synchronized intermittent mandatory ventilation (SIMV) is a hybrid of AC and PSV. The primary difference between AC and SIMV involves the spontaneous breaths. In AC, every patient-initiated breath receives full support up to the set tidal volume. In SIMV, a fifth parameter is set: pressure support. This value is analogous to the inspiratory positive airway pressure setting on BIPAP and provides a set level of pressure support for all spontaneous breaths. Thus, in SIMV, spontaneous breaths above and beyond the set rate generate whatever the patient is capable of doing with the applied pressure support. Notably, if the patient is fairly deeply sedated and/or the rate is set high enough, SIMV is essentially equivalent to VC because mandatory breaths are delivered at a set volume. On the contrary, if the rate is set low enough, the mode is essentially equivalent to PSV, perhaps with a minimal number (say, 2) of sigh breaths per minute. Those who advocate for the regular use of SIMV suggest that the benefit is in the ability to gradually wean between these two. Whether AC or SIMV forms the "default" mode of mechanical ventilation in an ICU is typically practitioner and unit specific.

Advanced Modes of Mechanical Ventilation

High-Frequency Oscillatory Ventilation

High-frequency oscillatory ventilation is an infrequently used mode involving extremely low tidal volumes at a high rate. It has been used as a salvage mode and/or a bridge to ECMO in severe ARDS. Although the concept behind this mode would seem to make physiologic sense in ARDS, clinical trials have not shown benefit.[50] There may be benefit in the pediatric population, but that topic is beyond the scope of this chapter.

Airway Pressure Release Ventilation and Bilevel Positive Airway Pressure Ventilation

Both APRV and bilevel ventilation provide two levels of CPAP that allow a mixture of spontaneous and ventilator-mandated breaths. They minimize the pressures seen by the alveoli and are thus most commonly used in patients with significantly reduced lung compliance, such as patients with ARDS. Specifically, APRV consists of a high CPAP (P_H) for a greater period of time (T_H), which then falls to a lower pressure (P_L) for a shorter period of time (T_L). This may be particularly useful in patients with severely noncompliant lungs and/or a large chest wall who suffer from frequent derecruitment. Bilevel is similar, but with a longer T_L. The specifics of these settings are beyond the scope of this text, but in brief, the P_H is set at a level to ensure oxygenation, whereas P_L and T_L are set to ensure adequate ventilation but not to allow for derecruitment. Opponents of these modes maintain that they can achieve similar results by adjusting the inspiratory and expiratory times in AC with resultant inverse ratio ventilation. Although these modes are still infrequently used compared with the other modes described earlier, there may be an appropriate population for which this is beneficial. A recent meta-analysis of nearly 19 years' worth of studies in patients with acute hypoxemic respiratory failure suggested a mortality benefit to APRV as compared with more conventional modes, although there was no difference in the need for rescue maneuvers such as prone positioning or ECMO.[51]

Extracorporeal Membrane Oxygenation

In patients with entirely refractory hypoxemia, ECMO may be considered. A detailed discussion of ECMO is beyond the scope of this chapter, but briefly, ECMO may be VA or venovenous (VV); the former is often used for those with concomitant cardiac dysfunction, and the latter is most often used for those with isolated lung pathology and hypoxia. An inflow cannula carries blood from a central vein, usually a common femoral vein, to an oxygenator, which both oxygenates and removes CO_2 through a membrane. This is done by diffusion, with "sweep gas" carried on the other side of the membrane. Blood then returns to the body via an outflow cannula, either to a central vein (common femoral or internal jugular) or artery (common femoral or, in the case of "central cannulation," the aorta). The use of ECMO may be controversial in some cases, particularly in those patients whose ability to recover is questionable; the technology should be considered a "bridge" therapy. However, the landmark CESAR (Efficacy and Economic Assessment of Conventional Ventilatory Support versus Extracorporeal Membrane Oxygenation for Severe Adult Respiratory Failure) trial suggested a mortality benefit to ECMO in patients with acute hypoxemic respiratory failure, and this is now a generally accepted indication.[52]

Extubation or Tracheostomy

Unless significant hemodynamic instability or other considerations prevent it, one should always be weaning the patient from the ventilator. The details of weaning techniques may vary by provider or center, but the overall idea is to slowly reduce the amount of support received by the patient in conjunction with increasing the amount of "work" the patient must do on their own. For example, when the patient is awake enough, a volume-controlled mode might be transitioned to a pressure support (spontaneous) mode, followed by a slow weaning of the amount of pressure support being provided, such that the patient is required to provide more of the work.

The weaning process, of course, culminates with extubation. The decision to extubate a patient is based on the following concepts:

1. Is the patient's airway patent (and can they protect it)?
2. Can the patient sufficiently oxygenate and ventilate?

In assessing airway patency, a leak test is performed. After deflation of the endotracheal tube cuff, a loss of 10% to 20% of the ventilated volume should be observed. If it is not, this suggests airway swelling to the degree that extubation may be perilous. IV steroids and reassessment in 24 hours are generally employed, although in some cases (particularly if there is a persistent lack of cuff leak over multiple days), extubation may be performed anyway with adequate precautions and preparations for reintubation. The patient must also be able to protect their airway, which is evaluated by the patient's GCS score and/or their ability to follow commands. Lack of ability to follow commands is not an absolute contraindication to extubation, particularly in neurosurgical patients; however, such decisions should be made by experienced clinicians.

There are numerous means of assessing the oxygenation and ventilation capabilities of the intubated patient. The successful tolerance of a spontaneous breathing trial is the best predictor of successful extubation. A spontaneous breathing trial is performed by placing the patient on a minimal amount of PSV, the standard for which varies by institution. For example, a patient may be placed on PSV 7/+5 at 40% FiO_2. Such settings essentially only compensate for the resistance of the endotracheal tube itself; it should be noted that the amount of pressure support that is considered "minimal" may vary with the size of the endotracheal tube. The rapid shallow breathing index (RSBI) is another commonly employed measure. While the patient is on pressure support, it is calculated by dividing the respiratory rate by the tidal volume (L). A variety of cutoff values have been used, but for example, an RSBI of less than 105 may be considered predictive of a successful extubation. However, a recent meta-analysis of data using a variety of cutoffs (nearly all of which were less than 105) suggested only moderate sensitivity and poor specificity of this metric.[53] Other respiratory mechanics, such as respiratory rate <25, negative inspiratory force more negative than −20 cm H_2O, tidal volume >5 cc/kg, minute ventilation <10 L/min, and vital capacity >10 cc/kg, have been used to predict successful extubation.

If a patient is likely to remain intubated for an extended period of time, conversion to a tracheostomy should be considered. Although the data on when to perform a tracheostomy are debatable, a commonly used date for evaluation is on mechanical ventilator day 7. Advocates for early tracheostomy cite decreased sedation needs, decreased airway risks, and more expedient liberation from the mechanical ventilator as benefits.

Pulmonary Pathology

Pulmonary Embolism

Pulmonary emboli primarily cause issues by two mechanisms: (1) increase in PVR with or without right heart strain and (2) increased dead space ventilation and resultant hypoxia. Prevention is the best weapon and should include early ambulation, intermittent pneumatic compression devices, and prophylactic low-level anticoagulation in at-risk populations (which includes nearly all surgical patients). The treatment consists of supplemental oxygen, along with systemic anticoagulation (heparin infusion or weight-based low-molecular-weight heparin) to prevent clot propagation. In severe cases, intubation, catheter-directed thrombolysis, pulmonary embolectomy, or ECMO may be required.

Pneumonia

Pneumonia is diagnosed by a new infiltrate on chest radiograph together with fever, leukocytosis, and/or purulent secretions. However, these findings are common in the ICU, and this clinical diagnosis can be much more difficult than it may seem.

Community-acquired pneumonia. The recommended treatment of community-acquired pneumonia is a β-lactam combined with a macrolide. Patients with severe disease, including those with septic shock and respiratory failure requiring mechanical ventilation, as well as those empirically treated for methicillin-resistant *Staphylococcus aureus* (MRSA) or *Pseudomonas,* should undergo sputum culture and blood culture.[54]

Ventilator-associated pneumonia. The most recent joint American Thoracic Society and Infectious Diseases Society of America clinical practice guidelines recommend abandoning the term *hospital-acquired pneumonia,* but ventilator-associated pneumonia (VAP) remains a distinct entity and is defined as pneumonia diagnosed after a patient has been mechanically ventilated for more than 48 hours.

Before initiating therapy in VAP, it is critical to send cultures (bronchoalveolar lavage). Patients with VAP are at high risk for multidrug-resistant organisms, and any patients with septic shock, ARDS, 5 or more hospitalization days, and/or renal replacement therapy should be covered with broad-spectrum antibiotics, until cultures allow targeting of therapy, for a total of 7 days. Patients without these risk factors should be treated with a single agent covering *Pseudomonas,* other gram-negative bacilli, and methicillin-sensitive *S. aureus*. However, it should be noted that local practices, formularies, and antibiotic resistance patterns vary widely throughout the United States and the world. Development of guidelines in conjunction with an ICU pharmacist will lead to improved quality of care and outcomes.

A key in managing VAPs is prevention. All patients should have the head of the bed elevated to 30 to 45 degrees. Patients on a mechanical ventilator should also have daily chlorhexidine rinses and interruptions of sedation. The ultimate prevention measure for VAP is liberation from the mechanical ventilator as early as safely possible.

Acute Respiratory Distress Syndrome

ARDS is an inflammatory response of the lung to multiple inciting factors, including blood product transfusions, sepsis, severe pancreatitis, trauma, and bleeding and/or hypotension. It is characterized by decreasing ability to oxygenate and decreased compliance ($\Delta V/\Delta P$) of the lung. The so-called Berlin definition involves bilateral infiltrates on chest radiograph or CT scan, a PaO_2-to-FiO_2 ratio of <300 (<300 is mild, <200 is moderate, and <100 is severe), a known clinical insult within 7 days before the diagnosis, and an explanation for pulmonary edema other than heart failure or fluid overload. Although the last criterion formerly required the measurement of a wedge pressure, objective assessment may now include other means (e.g., ultrasound).[55]

The management of ARDS revolves around mechanical ventilator settings. It consists of several goals:

- 6- to 8-cc/kg tidal volumes
- PaO_2 55 to 80 mm Hg or SpO_2 88% to 95%
- Plateau pressure ≤30 cm H_2O
- pH 7.30 to 7.45

There are many adjuncts to assist in meeting oxygenation requirements. Diuresis and optimization of fluid status to reduce any extrapulmonary edema are a sensible first step. Additionally, deep sedation and/or neuromuscular blockade with paralytics can be employed to ensure lack of any ventilator asynchrony, although some authorities maintain that this step is unnecessary if sedation is sufficiently deep. Finally, prone positioning is one of the few options that have been shown to reduce mortality in a randomized controlled trial.[56] However, this intervention should be used with caution and in a unit with personnel experienced in this technique. Placing a patient prone significantly reduces access, and turning a patient who has many lines and other attachments is not a risk-free endeavor. Close coordination with nursing staff and all ancillary staff is required. If this method is used, it should be used early in the course of ARDS.

ECMO serves as a final option for refractory ARDS. As noted earlier, the CESAR trial documented reduced mortality for patients with ARDS referred to ECMO centers. Notably, approximately 25% of the group of patients transferred for possible ECMO did not actually receive ECMO. The more recent Extracorporeal Membrane Oxygenation for Severe Acute Respiratory Distress Syndrome (EOLIA) trial concluded that there was no significant benefit of ECMO.[57] It should be noted that this trial was stopped early, and the benefit or lack thereof remains unclear. Adoption of standard guidelines and algorithms at the institutional level is likely to be of benefit.

Steroids, inhaled nitric oxide, inhaled epoprostenol, and high-frequency oscillatory ventilation techniques have all been shown to have no mortality benefit and are not commonly used, although they do improve hypoxia. Similarly, the alternative modes of mechanical ventilation previously discussed, as well as inverse ratio ventilation, do not have a proven mortality benefit.

GASTROINTESTINAL SYSTEM

Nutritional Requirements of the Critically Ill Patient

The energy requirements of the critically ill patient are higher than the baseline caloric demands of the average patient because of the hypermetabolic state that is induced by acute stressors. Major trauma, surgery, burns, or critical illness such as sepsis, congestive heart failure, or respiratory failure induce a catabolic state with an increase in inflammation, cytokines, and subsequent loss of weight and lean body mass. Combined with underlying comorbidities, bed rest and inactivity, and poor oral feeding, it is common for the overall metabolic demands of a patient to exceed nutritional intake and result in malnutrition, poor healing, and an increase in complications.

The most recent (2021) American Society of Parenteral and Enteral Nutrition (ASPEN) guidelines for the critically ill patient recommend feeding 12 to 25 kcal/kg/day.[58] This represents a change from prior recommendations for higher-calorie feeding and is reflective of more recent evidence suggesting, at a minimum, a lack of harm of lower-calorie feeding, including The Augmented versus Routine approach to Giving Energy Trial (TARGET) trial of energy-dense versus routine enteral feeding.[59] Compared with carbohydrates and fats, protein requirements are considered proportionally higher and vital for wound healing, maintaining lean body mass and preventing its loss, and supporting immune function. That said, there is also recent evidence to suggest that high-protein feeding may not provide any benefit over lower-protein supplementation.[60] This is again reflected in the most up-to-date ASPEN guidelines.

Given that the serum markers of albumin, transferrin, and prealbumin are negative acute-phase reactants, in the setting of significant stress or trauma, their levels will decrease as a result of increases in vascular permeability and reallocation of hepatic protein synthesis. ASPEN recommends against using such markers as proxies for nutritional status, and their values should be interpreted in conjunction with a patient's hospital course and clinical status.

Without a single modality to reliably and accurately measure a patient's overall nutritional status, one must continue to assess the patient with a complete physical exam, use clinical judgment, and gather additional data from ancillary studies to develop an individualized and comprehensive plan for nutritional support. Further aspects of nutritional support, including enteral versus parenteral nutrition, are covered in Chapter 34.

Stress Ulcer Prophylaxis

The GI mucosa is highly sensitive to the hemodynamic alterations often experienced by the critically ill patient. Splanchnic hypoperfusion, mucosal ischemia, reperfusion injury, and decreased mucosal protection can all result in the formation of ulcerations that have the potential to bleed or cause perforation. Mechanical ventilation influences a patient's hemodynamics, especially in cases that use high PEEP and/or higher than normal tidal volumes. Increased intrathoracic pressures decrease venous return and right heart filling, thus decreasing CO. Gastric ulcerations can be found in up to 90% of patients after severe trauma or hypotension, but their consequence is not clear because only a small percentage of these patients go on to have clinically relevant GI bleeding.

Classically, patients requiring mechanical ventilation for greater than 48 hours and the development of coagulopathy have been identified as the two main risk factors associated with the formation of GI ulcerations and GI bleeding. These patients are often administered gastric acid suppressants such as proton pump inhibitors (PPIs), histamine-2 receptor antagonists, or gastric mucosa protective agents, either as prophylaxis or treatment. Additional clinical considerations for which prophylaxis may be given include patients with elevated intracranial pressures (Cushing ulcer), burns (Curling ulcer), high-dose corticosteroid use, chronic or high-dose NSAID use, and prior history of gastric ulceration or GI bleed.

PPIs and histamine-2 receptor antagonists are the main choice for prophylaxis and treatment. They are not without risk because gastric acid is a natural barrier against pathogens, and suppression is thought to lead to gastric and duodenal bacterial overgrowth, aspiration pneumonia, and increased survival rates of *Clostridioides difficile*. In a recent randomized trial comparing PPIs to histamine-2 receptor antagonists, there was no difference in mortality, hospital length of stay, or *C. difficile* infection, although there was a lower rate of clinically important upper GI bleeding with PPIs. Notably, however, there was significant crossover from the H_2-blocker group to PPIs.[61]

There is controversy regarding the necessity of near-universal GI prophylaxis in light of significantly improved ICU care and the practice of early enteral feeding for GI mucosal maintenance and protection, resulting in less frequent use. Given the paucity of evidence outside of patients on mechanical ventilation and those with coagulopathy, neurotrauma, and new use of steroids or NSAIDs, it may be reasonable to restrict prophylaxis to these groups.

The Open Abdomen

The open abdomen is increasingly common in the ICU. It results from several situations, most commonly damage-control surgery and abdominal compartment syndrome. Damage-control surgery is a technique whereby patients who are critically ill but require urgent surgery—most often in the setting of trauma—are taken to the operating room for temporization of injuries and brought to the ICU with a temporary abdominal closure for correction of coagulopathy, hypothermia, and acidosis. Once stabilized, the patient returns to the operating room, where definitive repairs are performed.

The techniques of damage control will be addressed in other chapters. The review here focuses on the critical care elements. The primary goal for these patients in the ICU should be to correct the physiology—that is, any acidosis, hypothermia, and/or coagulopathy. Historically, the majority of these patients were traumatically injured. Increasingly, the concept of leaving the abdomen open is being employed in emergency general surgery (EGS), although often for other reasons (abdominal sepsis, the desire for a "second look")—there may be less for the critical care practitioner to correct in these patients.

Outside of the correction of deranged physiology, considerations for ICU providers include fluid management. The overuse of large-volume crystalloid resuscitation may result in bowel edema that decreases the ability to close the abdomen. The judicious use of such resuscitation, in addition to being generally helpful in ICU patients, will benefit in this regard. There has been some interest in the use of hypertonic saline for resuscitation, with the idea that this "draws fluid" out of the bowel and into the vasculature, facilitating closure. This idea is largely based on a small, retrospective study without subsequent high-quality evidence. The benefit of doing this may simply be the result of lower volumes of crystalloid. Finally, an emerging area of research on this front is the use of direct peritoneal resuscitation (DPR), in which a hypertonic (peritoneal dialysate) solution is used to reduce edema and mitigate inflammatory mediators in the bowel. This DPR concept may see increased use in the coming years.

HEPATIC SYSTEM

Cirrhosis

Cirrhosis is characterized by chronic liver inflammation that replaces normal liver parenchyma with diffuse fibrosis. The most common causes are alcohol-related liver disease, nonalcoholic fatty liver disease, hepatitis B and C, and autoimmune diseases. The gold standard for assessing the presence and cause of liver fibrosis is a liver biopsy. Liver elastography and magnetic resonance imaging (MRI) can be used to determine the degree of fibrosis. The presence of symptoms is termed *decompensated cirrhosis.*

Physical exam findings indicative of cirrhosis are typically seen in patients with decompensated disease. Exam findings include scleral icterus, gynecomastia, loss of secondary sexual characteristics, ascites, spider angiomata, and caput medusae.[62] Laboratory findings include either low or high transaminases, high bilirubin (typically direct bilirubinemia), hyponatremia, coagulopathy (elevated partial thromboplastin time [PTT] and international normalized ratio [INR]), elevated creatinine, low albumin, anemia, and thrombocytopenia.

There are two main scoring systems to estimate mortality risk in patients with cirrhosis. The Child-Turcotte-Pugh score categorizes patients into A, B, or C classes based on a patient's albumin, bilirubin, INR, amount of ascites, and degree of encephalopathy. Critics of this scoring system note that there are two subjective measures (amount of ascites and degree of encephalopathy), which can make scoring inconsistent and easy to manipulate. The 1-year survival ranges from 100% for class A to 45% for class C cirrhotic patients. Postoperative mortality after nonhepatic surgical procedures ranges from 10% for class A to 63% for class C.[63] Several studies have shown that the Acute Physiology and Chronic Health Evaluation (APACHE II) scores can be used in patients with cirrhosis to predict mortality in the ICU.[64,65] The Model for End-Stage Liver Disease (MELD) score was initially developed to predict mortality after a transjugular intrahepatic portosystemic shunt (TIPS) but has now been useful for determining surgical risk and for transplantation listing. This scoring system contains objective variables such as INR, creatinine, and bilirubin. Although not included in the original model, hyponatremia was found to be a significant predictor of 3-month waiting-list mortality and has been shown to be a predictor of ascites and renal dysfunction. Patients with cirrhosis and hyponatremia have been shown to have elevated renal artery resistances, elevated renin and aldosterone, and reduced MAP, all of which are causes of ascites and renal failure.[66,67] Subsequently, a new scoring system called *MELD-Na,* which added sodium to the model (an independent predictor of mortality in cirrhosis), is now being used for transplant organ allocation.

Portal Hypertension

There are several sequelae of decompensated cirrhosis, which all begin with the development of portal hypertension. The first step to the development of portal hypertension results from changes in hepatic architecture that create increased resistance in the portal system. In addition, the hepatic sinusoids produce less nitric oxide, a potent vasodilator, creating a shift in the balance of vasoconstrictive and vasodilatory substances and causing net vasoconstriction in the portal system. In contrast, the production of nitric oxide in the splanchnic circulation is increased (from shear stress and bacterial translocation), leading to splanchnic vasodilation, which decreases effective circulating blood volume, creating hypotension and an increase in portal flow. The combination of these factors leads to portal hypertension. The PREDESCI trial, a randomized, double-blind, placebo-controlled trial, showed that patients with clinically significant portal hypertension have a decreased risk of decompensation, particularly the development of ascites, with the use of β-blockers compared with placebo.[68] Further analysis has shown that carvedilol outperforms propranolol, leading to a new consensus guideline that carvedilol is the β-blocker of choice in clinically significant portal hypertension to prevent decompensation.[69] β-blockers work by both decreasing CO (β1 receptors) and causing splanchnic vasoconstriction (β2). Carvedilol has the additional benefit of having some α1 blockade effects, which also helps to reduce the hepatic venous pressure gradient.[70]

Ascites

Portal hypertension causes several pathologies, the most common being ascites. This is defined as the accumulation of fluid in the peritoneal space. This occurs because of several factors. The decrease in systemic effective circulating volume, as described earlier, causes an increase in catecholamine release and stimulates the renin-angiotensin-aldosterone system (RAAS). This promotes sodium and water retention and a subsequent increase in plasma volume. Given the splanchnic vasodilation and the portal hypertension, this volume is preferentially retained in the splanchnic system, which increases the hydrostatic pressure gradient and moves fluid from the splanchnic circulation to the peritoneal space. The degree of ascites is categorized into three grades: grade 1 is mild ascites detected on ultrasound alone; grade 2 is moderate ascites, defined as the presence of abdominal distension; and grade 3 is severe ascites, defined as a tense abdomen with a fluid wave.[71] When the cause of ascites is not obvious, a serum-ascites albumin gradient (SAAG) can be calculated (serum albumin concentration – ascites albumin concentration). A SAAG of $\geq$1.1 g/dL indicates portal hypertension as the etiology of the ascites. Treatment of portal hypertension–induced ascites includes a low-salt diet, sodium restriction, and diuretics. Commonly used diuretics are furosemide (to decrease sodium reabsorption in the thick ascending limb) and spironolactone (given that aldosterone plays a part in the ascites pathway). For grade 3 ascites, the immediate treatment is large-volume paracentesis followed by volume expansion with 25% albumin (6–8 g/L of fluid removed).[71] This will help to prevent postparacentesis circulatory dysfunction, which is characterized by renal failure and increased mortality.

Spontaneous Bacterial Peritonitis

An increase in bacterial translocation in the presence of extra fluid in the peritoneal cavity can lead to spontaneous bacterial peritonitis (SBP). Clinical signs can be nonspecific but generally include signs of infection with or without abdominal pain and gastrointestinal symptoms. The diagnosis is made based on ascites fluid analysis. An ascites fluid neutrophil count of $>$250 cells/μL is diagnostic of SBP, and initial treatment includes supportive measures along with intravenous antibiotics. The choice of antibiotics is based on the institution's resistance patterns but should cover a broad spectrum of bacteria. Indications for SBP prophylaxis (typically ciprofloxacin or trimethoprim-sulfamethoxazole) are an active GI bleed, prior history of SBP (may require lifelong prophylaxis), or ascites fluid protein $<$1.5 g/dL.

Varices

When portal pressures exceed 12 mm Hg, reversal of flow occurs in the portal/splanchnic circulation and creates varices (dilated veins), typically in the stomach and esophagus. If these veins rupture as a result of excess wall tension, they can cause variceal hemorrhage. Initial therapy for variceal hemorrhage should be aimed at restoring plasma volume with blood, antibiotics for 7 days to prevent secondary infections, and a somatostatin analogue (e.g., octreotide) for 3 to 5 days. Somatostatin analogues cause splanchnic vasoconstriction and a decrease in portal inflow, reducing the risk of continued hemorrhage and active bleeding. After a secure airway is established, the mainstay of therapy is to stop the hemorrhage. For a temporizing measure, balloon tamponade may be attempted with a Sengstaken-Blakemore tube. The tube is inserted through the mouth or naris until about 50 cm. The gastric balloon is insufflated with 100 cc of air, and a radiograph is used to confirm a position below the diaphragm. Once confirmed, the balloon is filled to its total amount (for a typical tube, 250 cc), and tension is placed on the tube to secure it in place at the gastroesophageal junction. For continued bleeding, the esophageal balloon is then inflated. This can be left in place for up to 24 to 48 hours, but it must be acknowledged that any amount of time that the esophageal balloon is inflated increases the risk for esophageal ischemia and perforation. The definitive treatment for variceal bleeding is esophageal band ligation or sclerotherapy when ligation is not feasible. Prevention of variceal hemorrhage includes nonselective β-blockade and esophageal band ligation. TIPS is reserved for refractory cases or when there is a portal vein thrombus because TIPS has been associated with an increase in portal vein recanalization in those cases.[72]

Transjugular Intrahepatic Portosystemic Shunt

Patients with refractory ascites or recurrent variceal bleeding may meet the criteria for TIPS. For this procedure, access is obtained through the right internal jugular vein, a hepatic venogram is performed, the portal veins are identified, and a stent is deployed to connect the high-resistance portal system to the low-resistance hepatic/systemic system (i.e., shunting blood away from the portal circulation). Contraindications for TIPS include heart failure and advanced liver disease with a MELD of $>$18. TIPS has been shown to decrease mortality in patients with severe bleeding, ascites, and hepatorenal syndrome.[73] However, TIPS is associated with up to a 20% risk of new or worsened hepatic encephalopathy. Hepatic encephalopathy is a risk with all portosystemic shunts because the ammonia that is produced by the bowel gets transported directly into the systemic circulation, bypassing even the small amount of metabolism that would have been accomplished by the liver.

Hepatic Encephalopathy

Hepatic encephalopathy is defined as potentially reversible neuropsychiatric abnormalities secondary to hepatic dysfunction and/or portal shunting.[62] The accumulation of ammonia (NH_3) has been implicated as the primary factor in the development of encephalopathy. Ammonia is the byproduct of protein degradation in the bowel. The liver converts ammonia to urea using the urea cycle. When this cycle is not functioning optimally (e.g., in cirrhosis), an accumulation of ammonia occurs in the blood. Ammonia then crosses the blood-brain barrier and is converted to glutamine by astrocytes. Glutamine acts as an osmotic load and causes cellular swelling, damage, and impaired synaptic transmissions.[74] Clinical features include lethargy, disorientation, asterixis, and in more severe cases, depressed consciousness and stupor. The degree of encephalopathy is graded from grade 0 (no encephalopathy) to grade 4 (coma). Grade 2 encephalopathy or higher occurs in up to 40% of all patients with cirrhosis.[75] The treatment involves reducing the production of ammonia in the bowel to stop the accumulation at its start. Lactulose is a nonabsorbable disaccharide and is broken down by the bacteria *Lactobacillus acidophilus* and acts to acidify the bowel. This causes eradication of the gram-negative aerobic bacilli that are essential to converting protein into ammonia. Additionally, acidification of the bowel decreases the absorption of ammonia into the bloodstream.[74] The European Association for the Study of the Liver (EASL) guidelines recommend starting and titrating lactulose to 2 to 3 bowel movements per day for encephalopathy prophylaxis after an episode of overt hepatic encephalopathy.[75] Rifaximin is an antibiotic that also works to eradicate the gram-negative bacilli responsible for ammonia generation in the bowel. Guidelines recommend using rifaximin as an adjunct to lactulose for encephalopathy prophylaxis.[75]

Hepatorenal Syndrome

Hepatorenal syndrome (HRS) is defined as renal failure that occurs in patients with cirrhosis, typically after an episode of sepsis or a hyperinflammatory state. Although the mechanism is not entirely understood, it is thought to occur because of splanchnic vasodilation and reduced CO. This causes renal arterial vasoconstriction, resulting in hypoperfusion and a reduction in the glomerular filtration rate (GFR). Sepsis is also associated with splanchnic vasodilation, but a new theory suggests that proinflammatory cytokines may also play a role by inducing microvascular dysfunction in the renal tubules, indirectly causing an increase in RAAS and further lowering GFR.[71] The major criteria for the diagnosis of HRS are renal dysfunction in the setting of cirrhosis, not explained by other causes and not responsive to diuretic withdrawal and volume expansion. Although urine studies can vary, the most common findings are a urine sodium of $<$10 mmol/L and urine osmolality greater than plasma osmolality because tubular function is typically preserved.[76] HRS is categorized into two types: HRS–acute kidney injury (HRS-AKI) (formerly type 1) is defined as rapidly progressing deterioration of renal function (over 1–2 weeks), and HRS–nonacute kidney injury (HRS-NAKI) (formerly type 2) is characterized by more gradual renal dysfunction, resistant to diuretics, resulting from refractory ascites.[77] The management of HRS includes a splanchnic vasoconstrictor to increase renal perfusion pressures (vasopressin analogue) and a volume expander (albumin). Terlipressin is a vasopressin analogue that has recently been approved for use in the United States as first-line therapy for the treatment of HRS-AKI and is continued for up to 14 days after creatinine levels return to baseline.[77] The Multi-Center, Randomized, Placebo Controlled, Double-Blind Study to Confirm Efficacy and Safety of Terlipressin in Subjects With Hepatorenal Syndrome Type 1 (CONFIRM) trial, a phase III randomized placebo-controlled trial, compared terlipressin to placebo in patients with HRS-AKI and found an increased rate of HRS reversal in the terlipressin group when combined with albumin. However, terlipressin was associated with a risk of respiratory failure; therefore, oxygen levels should be monitored carefully.[78] Other management options for patients who do not respond to or cannot receive terlipressin are renal replacement therapy, TIPS, or liver transplant.

Portopulmonary Hypertension/Hepatopulmonary Syndrome

Portopulmonary hypertension (PPHT) should be considered in patients with portal hypertension who have right-sided heart failure from increased pulmonary artery pressures (PAPs) with normal pulmonary occlusion pressures (to rule out left-sided heart failure as the cause). PPHT is categorized as mild (mean PAP of 25–35), moderate (mean PAP of 35–45), or severe (mean PAP of $\geq$45).[71] Although the pathogenesis is poorly understood, the current understanding is that PPHT occurs because of pulmonary vascular vasoconstriction from increased endothelin-1 released and not metabolized by the cirrhotic liver and decreased prostacyclin from pulmonary endothelial cells. Treatment includes endothelin receptor antagonists (e.g., Bosentan), phosphodiesterase-5 inhibitors (e.g., sildenafil), and prostacyclin analogues (e.g., epoprostenol). Severe PPHT (mean PAP of $\geq$45) is an absolute contraindication to liver transplant because of very poor postoperative outcomes. To prevent patients from reaching that stage, MELD exception points are granted to patients with moderate PPHT. Studies have shown that up to 60% of patients who receive pre- and postoperative therapy are able to discontinue pulmonary hypertension medications over time after their liver transplant. However, compared with non-PPHT patients, PPHT MELD exception patients have worse 1-year mortality after liver transplant.[71]

RENAL

Anatomy and Physiology

The primary function of the kidney is to maintain homeostasis and metabolize toxins. The human kidneys make up less than 0.5% of the total body weight but receive 25% of the CO ($\sim$6 L/day). From anterior to posterior, the kidney is connected to the renal vein, artery, and pelvis/ureter. The kidney itself is contained in Gerota's fascia, and from superficial to deep, it contains the fibrous capsule, renal cortex, and renal medulla, which is made up of the renal pyramids and renal papilla. These lead to the minor and major calyx, which combine to form the renal pelvis and, subsequently, the ureter. The nephron, the functional unit of the kidney, contains the glomerulus and renal tubules, which span the cortex and medulla. The branch that enters the glomerulus is the afferent arteriole, and the branch that exits the glomerulus is the efferent arteriole. Blood flow is primarily directed to the cortex to optimize glomerular filtration (PO_2 in the cortex of $\sim$50 mm Hg), making blood flow very low in the medulla in order to preserve osmotic gradients (PO_2 in the medulla of $\sim$10–20 mm Hg). Despite wide fluctuations in renal arterial perfusion pressures (80–180 mm Hg), the renal blood flow, and therefore glomerular filtration, is closely autoregulated by the afferent and efferent arterioles.

The plasma that flows from the afferent to the efferent arterioles is filtered by the glomerulus. The GFR is determined by the rate of blood flow, the combination of hydrostatic and oncotic pressure gradients, surface area, and membrane permeability (normal GFR is $\sim$120 mL/min). The blood flow and hydrostatic pressures are controlled by either constriction or dilation of the afferent and efferent arterioles, determined by various hormones, such as angiotensin and prostaglandins. When renal perfusion pressures fall, renin is released from the juxtaglomerular cells (in the walls of the afferent arteriole), which converts angiotensin to angiotensin I in the liver, which is then converted to angiotensin II in the lungs, which causes vasoconstriction of the efferent arteriole, increasing the hydrostatic pressure at the glomerulus to maintain GFR. Similarly, prostaglandins cause vasodilation of the afferent arteriole to increase blood flow and hydrostatic pressure at the glomerulus to increase GFR.

The proximal tubule reabsorbs almost all of the glucose and amino acids and about 65% of the sodium (Na) and water. The luminal fluid then enters the loop of Henle in the medulla, made up of the descending loop and thick ascending limb. The descending loop contains aquaporins, which are water channels that allow water to passively travel along its gradient. Water travels from low osmolality in the lumen to high osmolality in the medulla. This osmotic gradient is created by the thick ascending limb. The thick ascending limb is impermeable to water but creates an ionic gradient between the lumen and medulla and reabsorbs Na and chloride (Cl). As the solutes increase the osmolality of the medulla, more water continues to be reabsorbed from the descending limb, which then causes more reabsorption of solutes from the thick ascending limb, all of which leads to a rise in osmolality to reach a maximum of 1200 mOsm/L in the deepest areas of the medulla. This is called the *countercurrent multiplier.* This creates the corticomedullary osmotic gradient. Once fluid leaves the ascending limb, it enters the distal tubule and collecting duct. Both reabsorb ions but are only permeable to water in the presence of antidiuretic hormone (ADH). In the presence of ADH, aquaporin channels are inserted into the apical membrane of the collecting tubule, and water is reabsorbed down its osmotic gradient. Disorders and management of electrolytes, such as sodium, potassium, calcium, and magnesium, are covered in depth in Chapter 33.

Acid-Base Regulation

The body pH is tightly regulated by the respiratory and renal systems. One of the main buffer systems in the body is the carbonic acid–bicarbonate buffer system. Carbon dioxide combines with water to form carbonic acid, which then dissociates into bicarbonate and a hydrogen ion with the help of carbonic anhydrase.

The respiratory system changes the pH by regulating how much CO_2 is expired. This system can alter the pH within hours. The renal system regulates pH by reabsorbing bicarbonate and excreting hydrogen. Hydrogen is excreted in the form of hydrogen ions or in the form of ammonium. Almost all the filtered bicarbonate is reabsorbed in the proximal tubule. This mechanism changes body pH over a longer period of time, on the order of days.

The pH of the body represents the concentration of hydrogen ions in the blood. There are two broad categories of systems that are evaluated when assessing the etiology of a patient's acid-base status: metabolic and respiratory. When evaluating an acid-base disorder, there is typically a primary disorder that is driving the imbalance, and the other system attempts to compensate. The compensation will always occur in the direction of normalizing the pH. The method for determining the primary disorder is to analyze the blood gas. The blood gas contains the pH, $PaCO_2$, and HCO_3^-. The direction of the pH is the disorder (i.e., acidosis or alkalosis). If the $PaCO_2$ and the pH change in opposite directions, it is a primary respiratory disorder, and if the pH and the HCO_3^- change in the same direction, then it is a primary metabolic disorder. If both exist, then it is a mixed respiratory and metabolic disorder. Normal values are as follows: pH, 7.35 to 7.45; $PaCO_2$, 35 to 45 mm Hg; and HCO_{3-}, 22 to 26 mEq/L. Equations can be used to calculate the expected compensatory response. If the expected compensatory response is different from the measured value, then there is likely a mixed acid-base disorder involving both systems.

Respiratory Acidosis

Respiratory acidosis is caused by hypoventilation, which decreases the amount of CO_2 exhaled and increases the $PaCO_2$. Metabolic compensation occurs when the kidneys increase bicarbonate reabsorption in the proximal tubules. For acute respiratory acidosis, the metabolic compensation will be very little:

$$\Delta HCO_{3-} = \Delta PaCO_2 \times 0.1$$

For chronic respiratory acidosis, the metabolic compensation is as follows:

$$\Delta HCO_{3-} = \Delta PaCO_2 \times 0.4$$

Respiratory Alkalosis

Respiratory alkalosis occurs in the setting of increased minute ventilation (respiratory rate and tidal volume). In acute respiratory alkalosis, the metabolic compensation is as follows:

$$\Delta HCO_{3-} = \Delta PaCO_2 \times 0.2$$

In chronic respiratory alkalosis, the metabolic compensation is as follows:

$$\Delta HCO_{3-} = \Delta PaCO_2 \times 0.4$$

Metabolic Acidosis

Metabolic acidosis is characterized by a primary reduction in bicarbonate (HCO_3^-) concentration. This occurs either by the addition of an acid that is buffered by HCO_3^-, loss of HCO_3^-, or addition of nonbicarbonate fluid that dilutes the bicarbonate concentration in the plasma. When an additional acid is buffered by HCO_3^-, an organic anion is created. This creates an anion gap (AG) metabolic acidosis. When bicarbonate is lost or diluted, chloride concentrations increase to preserve electroneutrality. This creates a non-AG metabolic acidosis. The AG is calculated as follows:

$$AG = [Na^+] - [Cl^-] - [HCO_3^-]$$

A normal AG is between 3 and 11. There is an additional formula that has been suggested that corrects for hypoalbuminemia, but for simplicity, the previous formula should suffice. If the AG is higher than the normal AG, then the disorder is considered an AG metabolic acidosis. Common causes are typically remembered by the mnemonic "MUDPILES": methanol, uremia, diabetic ketoacidosis, paracetamol, isoniazid, lactic acidosis, ethanol/ethylene glycol, and salicylates. In order to determine whether there are two metabolic acid-base disorders, a delta gap (or gap-gap ratio, not listed here) can be calculated.

$$\text{Delta gap} = (\text{normal AG} - \text{calculated AG}) - (\text{normal } HCO_3^- - \text{calculated } HCO_3^-)$$

If the delta gap is significantly positive (>+6), then there is an associated metabolic alkalosis present, and if the delta gap is significantly negative (<–6), then there is an associated non-AG metabolic acidosis also present. This is an extremely simplified method of evaluating a very complicated buffering system in the body, and it makes several assumptions, the main one being that bicarbonate is the only buffering system in the body when in fact, there are several others, including phosphate, hemoglobin, and other plasma proteins.

Causes of non-AG metabolic acidosis include diarrhea, normal saline infusion, and renal tubular acidosis. The respiratory response to metabolic acidosis is a decrease in $PaCO_2$ by increasing the minute ventilation. The expected change in $PaCO_2$ is as follows:

$$\Delta PaCO_2 = 1.2 \times \Delta HCO_3^-$$

Initial decreases in pH are typically well tolerated and can actually assist in certain functions, such as oxygen unloading from hemoglobin. However, as the acidosis worsens, myocardial contractility is affected, and its response to catecholamines becomes blunted.[79]

Metabolic Alkalosis

Metabolic alkalosis is characterized by an increase in bicarbonate concentration in the plasma. This can occur by net loss of hydrogen ions (i.e., from the GI tract), addition of bicarbonate at a rate unable to be regulated/excreted by the kidneys, loss of fluid with low bicarbonate concentration (i.e., diuretics), or loss of fluid that leads to a contraction alkalosis. The theory behind contraction alkalosis is that a loss of plasma volume causes activation of the RAAS. Aldosterone causes an increase in bicarbonate reabsorption in the proximal tubule and an increase in hydrogen ion excretion in the distal tubule. The expected change in $PaCO_2$ in metabolic alkalosis is as follows:

$$\Delta PaCO_2 = 0.7 \times \Delta HCO_3^-$$

Acute Kidney Injury

Acute kidney injury (AKI) is defined as an increase in serum creatinine of ≥3 mg/dL over 48 hours, an increase in creatinine of ≥1.5 times baseline over 7 days, or a urine output of <0.5 cc/kg/hour over 6 hours.[80] AKI is categorized into three stages: stage 1, serum creatinine of 1.5 to 1.9 times baseline;

stage 2, serum creatinine of 2.0 to 2.9 times baseline; and stage 3, serum creatinine of 3 times baseline or initiation of renal replacement therapy (RRT).

The Kidney Disease Improving Global (KDIGO) guidelines recommend preventing AKI by ensuring adequate volume resuscitation using crystalloids rather than colloids, avoiding hypoglycemia and nephrotoxic agents, and giving intravenous fluids with contrast agents if at high risk for contrast-induced nephropathy. RRT is indicated for toxin removal or in the setting of AKI that has resulted in severe complications, including hyperkalemia, acidosis, or fluid overload. Several studies have evaluated early versus standard timing of RRT initiation. A recent multinational, randomized controlled trial in ICU patients with AKI compared patients who received RRT within hours versus when standard clinical criteria were met. They found no difference in mortality and a higher dependence on dialysis and adverse events in the early RRT group.[81]

Renal Replacement Therapy

Methods of RRT are broadly categorized into hemodialysis and peritoneal dialysis. Hemodialysis is divided into continuous versus intermittent methods. Continuous RRT (CRRT) is indicated for patients who cannot tolerate large hemodynamic changes. The basic flow of hemodialysis involves the following: Blood is removed from the patient and flows through a blood pump, then travels through a filter with a semipermeable membrane where fluid/solutes are removed (effluent), and the remainder flows back into the patient. Methods of fluid and solute removal include ultrafiltration, which is the removal of fluid across its pressure gradient as determined by the combination of hydrostatic and oncotic pressures; convection, which is the removal of solutes that get dragged with high flows of fluid ("solute drag"); and diffusion, which is the movement of solutes down their concentration gradients (this involves a dialysate on the other side of the membrane to establish a steady concentration gradient). Slow continuous ultrafiltration (SCUF) uses ultrafiltration only and is used to remove fluid from patients. The blood flow is set at a slower rate so that little to no solute drag (convection) is achieved. Continuous venovenous hemofiltration (CVVH) is similar to SCUF except that the blood flow is much higher, and this causes faster ultrafiltration of fluid and creates a convection force to drag solutes across the membrane as well. This works well for all sizes of molecules and for electrolyte/acid clearance. This mode requires that a lot of fluid be filtered out in order to achieve appropriate solute clearance, so replacement fluid is added to the circuit to give fluid back to the patient. Replacement fluid can be placed prefilter (dilutes the blood and decreases clearance but decreases filter clotting), postfilter (improved clearance but increases filter clotting), or more likely, a combination of the two. Continuous venovenous hemodialysis (CVVHD) adds a dialysate around the semipermeable membrane in the filter to clear solutes using diffusion. The amount of solute clearance is based on the concentration of each solute in the dialysate, which determines the concentration gradient. Because solutes are being filtered by diffusion and not convection, this does not require a large amount of fluid loss and therefore does not require replacement fluid to be given back. Finally, continuous venovenous hemodialysis filtration (CVVHDF) is a combination of all the different modes. Intermittent hemodialysis (iHD) uses dialysis/diffusion for removal of solutes and can also remove fluid. iHD uses much higher blood flow rates over a shorter period of time. This can cause fluctuations in hemodynamics compared with a slow, continuous blood flow rate over 24 hours, as in CRRT.

HEMATOLOGIC SYSTEM

Transfusion Strategies

Anemia is common in all ICUs, largely secondary to so-called "anemia of chronic disease" and frequent phlebotomy, but in the surgical ICU, more nefarious etiologies, such as trauma and GI bleeding, must be considered. Generally speaking, evidence supports a restrictive transfusion strategy, or transfusing to a goal hemoglobin of 7 g/dL. Some have considered a higher goal in GI bleed and traumatic brain injury (TBI) patients, although this is not supported. The one special population in which a hemoglobin goal of 8 g/dL may make sense is those with stable cardiovascular disease. It is important to note that transfusion-related complications can occur and include allergic or anaphylactic reactions, fluid overload, iron overload, transmission of blood-borne infections, transfusion-related acute lung injury, immunosuppression, hypersensitivity reactions, and life-threatening hemolysis from ABO incompatibility.

On the other hand, it is imperative to understand that a declining hemoglobin is a late manifestation of active bleeding. In trauma patients or others with reason to suspect active bleeding, transfusion should be based on other clinical parameters, such as tachycardia, hypotension, and lactate, and intervention to achieve hemostasis should be pursued. Approaches to transfusion in hemorrhagic shock are detailed further in the cardiovascular section earlier in the chapter, but component therapy should be balanced, and whole blood should be considered, if available. In massive transfusion scenarios, TEG may be beneficial.

Viscoelastic Testing

Viscoelastic testing (VET), which can be performed by either TEG or ROTEM, was devised in the 1950s to assess the clotting capability of whole blood. Despite its potential applications, its widespread use was limited by a lack of accessibility and complexity in testing, and thus, the more common and conventional coagulation tests, such as PT/INR, PTT, platelet count, and fibrinogen level, were preferred. It was not until the 1980s, when testing became more practical, quicker, and reproducible, that TEG was used to guide resuscitation during transplant and cardiac surgeries and was found to decrease the total administration of blood products and mortality.

Currently, TEG and ROTEM are used with increasing regularity in the bleeding patient. The advantage of VET over traditional coagulation tests is that VET is a real-time, detailed functional assay that provides information about clot formation, propagation, strength, and lysis.

Traditional TEG involves a pin suspended in a sample of patient blood, oscillating at a fixed frequency. As a clot forms and slows the movement of the pin, the torque is measured by a transducer and traced into the thromboelastogram. The more recent iteration of the TEG system (TEG 6s, Haemonetics) involves vibration of the blood sample itself and a light detector that measures meniscus motion as clot forms.[82] The thromboelastogram shows four key values—clot formation, clot propagation, clot strength, and thrombolysis—as shown in Fig. 46.1. ROTEM evolved from TEG technology and has slightly different parameters and reagents that can be used to evaluate various aspects of coagulation. Data on the use of TEG in EGS patients are still emerging, but data for its use in trauma patients, particularly those with massive exsanguination, continue to be promulgated. It may be most useful after hemorrhage control in the ICU, where residual clot dysfunction can be uncovered and treated. The 2020 EAST guidelines conditionally

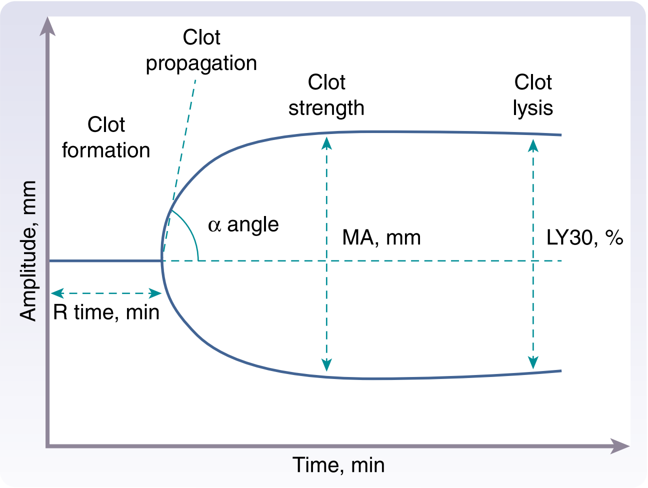

FIGURE 46.1 Thromboelastogram parameters. *R time* represents the time to clot formation; a prolonged R time may indicate a need for plasma transfusion. Clot propagation is represented by the *α angle,* with a low angle indicating a need for cryoprecipitate. The strength of the clot is shown by the maximum amplitude *(MA),* a representation of platelet function. Lastly, the LY30, or percent decrease of tracing width at 30 minutes, measures thrombolysis and potential need for tranexamic acid.

recommend its use in bleeding trauma, surgical, and ICU patients with suspected coagulopathy.[43]

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is a life-threatening complication that occurs in 1% to 5% of patients exposed to any of the forms of heparin.[83] The patient produces platelet-activating IgG antibodies to the complex of heparin bound to circulating platelet factor-4 (PF4). These immune complexes release additional prothrombotic molecules, thus propagating platelet consumption. The reticuloendothelial system eliminates these circulating immune complexes, leading to thrombocytopenia.

In order to make the diagnosis of HIT, the patient must exhibit the classic clinical signs of HIT in conjunction with appropriately timed heparin exposure. Thus, a description of the clinical features also serves as a description of initial diagnostic criteria. One of the most commonly used scores to diagnose HIT is the "4 Ts score," with variable points for **T**hrombocytopenia, **T**iming, **T**hrombosis and systemic events, and o**T**her causes of thrombocytopenia.

Classically, the degree of thrombocytopenia should be a reduction of >50%, although 10% of patients will have a 30% to 50% reduction. The most suspicious timing is 5 to 10 days from heparin exposure, although a more rapid onset may occur in patients previously exposed to heparin. Also, 25% to 68% of patients will have a thrombotic event, which may be apparent before the onset of thrombocytopenia. Finally, the presence of other, more plausible causes of thrombocytopenia should be considered because this may lower the pretest probability.

If the 4 Ts score indicates a low probability of HIT, heparin should be continued, and other causes of thrombocytopenia should be considered. If intermediate or high risk, heparin should be discontinued, alternative anticoagulation (often a direct thrombin inhibitor [DTI], such as argatroban or bivalirudin) should be started, and further testing should be undertaken.

Laboratory assessment for HIT generally begins with an enzyme-linked immunosorbent assay (ELISA), which is sensitive but not specific for HIT. If negative, HIT is ruled out. If positive, a confirmatory serotonin release assay should be performed. Although a serotonin release assay is considered the "gold standard," it is not as readily available and requires testing in a reference laboratory.

Over 40% of patients in the ICU develop thrombocytopenia, but HIT is rarely the cause, with an overall incidence of only 0.02% to 0.45%. However, even with treatment, mortality rates associated with HIT can be as high as 14.5% to 25%. In any patient with clinical suspicion of HIT, it is prudent to avoid all heparin exposure until a definitive diagnosis is obtained.

Venous Thromboembolism

Critically ill patients are at high risk for developing venous thromboembolism (VTE) because they have all the components of the Virchow triad to some degree: endothelial injury, venous stasis, and hypercoagulability. VTE is a preventable cause of death that is common but often undiagnosed and clinically silent. All patients admitted to the ICU should be assessed for and treated against the development of VTE as recommended by the American College of Chest Physicians Evidence-Based Clinical Practice Guidelines.[84] Most cases in which thromboprophylaxis is held are due to physician perception that the risk of bleeding outweighs the risk of VTE. However, delays of over 24 hours in initiating pharmacologic VTE prophylaxis after ICU admission are associated with a threefold increase in VTE formation after major trauma.

Absolute contraindications to chemical thromboprophylaxis include active bleeding or intracranial hemorrhage, coagulopathy, and severe thrombocytopenia. However, in patients with relative contraindications, such as recent GI bleeding, recent surgery, and moderate thrombocytopenia, the decision to initiate chemical thromboprophylaxis must be made on a case-by-case basis. At a minimum, mechanical thromboprophylaxis should be provided by means of intermittent pneumatic compression devices. Mechanical compression is used to promote venous blood flow and is thought to activate tissue plasminogen and local fibrinolysis. When no absolute contraindications are present, chemical thromboprophylaxis should be administered because it has been proven superior to mechanical compression for the prevention of deep vein thromboses (DVTs) and PEs.

Perhaps the most often-discussed contraindication to chemoprophylaxis in ICU patients is TBI, out of concern for worsening intracranial hemorrhage. However, there is evidence to suggest that in most cases, particularly in cases of mild TBI, early chemoprophylaxis (24–72 hours) is associated with decreased thromboembolic events without an increase in neurosurgical interventions or death. In the subset of patients who might be considered to have the highest risk—patients who require neurosurgical intervention on presentation—there is evidence that early chemoprophylaxis is associated with an increased risk of needing a repeat neurosurgical operation, although the same study suggested an increased risk of thromboembolic events with delays in prophylaxis in these patients.[85] Needless to say, decision-making in this context is complex and should take place after a conversation with both trauma surgeons and neurosurgeons caring for the patient.

Low-molecular-weight heparin has been shown to be more effective than unfractionated heparin for the prevention of DVTs, but it is renally excreted; this should be considered in the setting of AKI or renal failure. Despite adherence to chemical thromboprophylaxis administration, obesity and proinflammatory states such as sepsis convey higher rates of VTE prophylaxis failure. In these cases, goal-directed therapy and titration of low-molecular-weight heparin dosing based on anti-Xa levels have been proven effective. As the Xa assays become more available, ensuring target levels is becoming more mainstream in trauma patients in general. In patients in whom chemical thromboprophylaxis is contraindicated for an extended period of time, one could consider placement of an inferior vena cava filter to prevent large DVT embolization and clinically significant PEs.

ENDOCRINE SYSTEM

Glucose Control

Stress hyperglycemia, defined as hyperglycemia and insulin resistance in the setting of acute illness, occurs in up to 50% of patients in the ICU.[86] Hyperglycemia occurs because of an increase in catecholamines and cortisol, which increase gluconeogenesis in the liver, and inflammatory cytokines that create insulin resistance.[87] A certain amount of hyperglycemia may be protective by increasing the plasticity and ischemic resistance of cells, but as the glucose levels increase or become more chronic, it appears to increase morbidity and mortality.[87,88] Several studies have attempted to evaluate the benefit of tight glycemic control. The landmark study by the NICE-SUGAR investigators compared tight glycemic control (glucose 81–108 mg/dL) versus a more liberal target (glucose < 180 mg/dL) and found lower mortality with the more liberal strategy.[89] This was attributed to the higher incidence of hypoglycemia in the group with tight glycemic control. Based on the available evidence, the most important considerations in glycemic control are to prevent severe hyperglycemia, prevent hypoglycemia, and likely most importantly, prevent large fluctuations in glucose. With these considerations, the current standard practice is to employ some glucose control and to aim for a glucose of <180 mg/dL.

The next frontier of glucose control in the ICU is continuous glucose monitors. However, this method has not been shown to improve glycemic control (i.e., prevent hyperglycemia) but has been shown to decrease rates of hypoglycemia.[90,91] It was approved for emergency use during the pandemic, and with increasing implementation across hospitals, it may provide an avenue for further investigation.

Critical Illness Adrenal Insufficiency

The stress response is controlled by the hypothalamic-pituitary-adrenal axis (HPA). The hypothalamus senses stress in the body and releases corticotropin-releasing hormone (CRH), which stimulates the anterior pituitary to release adrenocorticotropic hormone (ACTH). ACTH stimulates the secretion of cortisol in the adrenal cortex.[92] In healthy patients, cortisol is released in a circadian rhythm, with its peak in the early hours of the morning and then gradually decreasing during the day. Cortisol then exerts a negative inhibitory effect on the hypothalamus and pituitary. Critical illness is marked by a loss of circadian rhythm, decreased adrenal synthesis/secretion of cortisol, decreased cortisol availability, tissue resistance to cortisol, and inhibition of ACTH synthesis through increased negative feedback mechanisms or medications.[93]

Critical illness-related corticosteroid insufficiency (CIRCI) is defined as the relative impairment of the hypothalamic-pituitary axis during critical illness.[94] Based on the low quality of evidence, guidelines recommend starting stress-dose steroids in patients in septic shock, not responsive to fluid, and on moderate- to high-dose vasopressor therapy.[94] Patients on chronic steroids for pathology related to inadequate HPA axis should also receive stress-dose steroids because they likely cannot mount a stress response. Patients on chronic steroids for reasons other than an HPA axis deficiency should receive their home-dose equivalent steroid dose and can be given a stress dose at the provider's discretion.[95,96] Guidelines recommend using a dose course that is long and low (IV hydrocortisone <400 mg/day for ≥3 days).[94] However, studies have shown mixed results regarding whether steroids have any effect on mortality in patients with septic shock, but there is some evidence that they may shorten the duration of shock.[38,97-100] Although not typically done in practice, these guidelines recommend testing patients for adrenal insufficiency with a high-dose ACTH stimulation test.

Thyroid Dysfunction

Thyroid-stimulating hormone (TSH) is released from the pituitary gland to stimulate the thyroid gland to produce thyroxine (T_4), which converts to its activated form, triiodothyronine (T_3). Thyroid hormones exert negative feedback on TSH secretion. TSH levels are the most reliable method of checking thyroid function; however, TSH is a negative acute-phase reactant and is often falsely depressed and inaccurate in the setting of acute illness.

Hyperthyroidism is defined as excess circulating thyroid hormones. This can be primary (due to excess thyroid activity) or secondary (due to HPA axis dysfunction). Thyroid storm is a rare form of hyperthyroidism, occurring in less than 0.2% of hospitalized patients, but it carries a 40% mortality rate.[101] The most common causes include Grave disease, amiodarone-associated thyrotoxicosis, and infection. Symptoms include hyperpyrexia, agitation/delirium, tachycardia, and high-output heart failure. The treatment is β-blockers (propranolol is the drug of choice in thyroid storm) to manage the tachycardia and agitation and antithyroid drugs, such as methimazole or propylthiouracil.

Hypothyroidism is also rare in the critical illness setting. Causes include autoimmune thyroiditis, HPA axis dysfunction, and drug induced. Symptoms include fatigue, muscle cramps, and constipation. There is also an increased risk of a pericardial or pleural effusion because of increased capillary permeability. A more severe form is myxedema coma, which is hypothyroidism plus depressed mental status. Treatment includes steroids (if adrenal insufficiency is also suspected) and thyroid hormone supplementation.

INFECTIOUS DISEASES

General Principles

Around 50% to 60% of ICU patients develop a nosocomial infection, defined as an infection acquired while receiving healthcare that was not present at admission.[102] The mortality reaches up to 35%, and nosocomial infections account for almost half of hospital costs.[101] The most common routes and locations of infection are pulmonary, abdominal, genitourinary, and bloodstream. These infections are more common in ICU patients, likely because of the number of invasive procedures these patients receive in addition to the immunosuppression that accompanies critical illness. The most common organisms are gram-positive bacteria, such as *S. aureus,* and gram-negative bacteria, such as *P. aeruginosa* and *Escherichia coli.*[102] Risk factors for the development of a nosocomial infection in the ICU include ICU length of stay (the risk doubles from 1 day to 1 week in the ICU) and severe medical comorbidities.

Sepsis

Sepsis is defined as an infection with organ dysfunction. This occurs because of an unregulated immune and inflammatory response. More specifically, the new definition is the presence of infection and a change in SOFA score of >2 points.[103] Septic shock is the addition of cardiovascular dysfunction, specifically hypotension despite fluid resuscitation, and the need for vasopressors. The precise pathophysiology is not clear but likely involves activation of both pro- and antiinflammatory cytokines and mediators. There is an overwhelming proinflammatory and immunosuppression response, both occurring at the same time but at different intensities based on comorbidities or infectious etiology. This explains the increased incidence and risk of additional nosocomial infections during and after sepsis recovery. Shock occurs because of alterations in microcirculation, leaky capillaries from the inflammatory response, and vasodilation that leads to altered distribution of systemic blood flow. This creates a mismatch between tissue oxygenation needs, which are higher in patients with sepsis/critical illness, and oxygen delivery, leading to shock. The combination is termed *distributive shock.*[103] Given the high mortality, early recognition can make all the difference. Sepsis can be harder to identify in ICU patients, given that traditional objective findings may be altered from other comorbid conditions. For example, patients may not mount a white blood cell count; may not develop a fever (if on CRRT or ECMO); and may have many other reasons for respiratory failure, altered mental status, and lactic acidosis that can mislead providers. When there is concern for or proven sepsis, the most recent Surviving Sepsis Campaign guidelines recommend resuscitation with 30 cc/kg of balanced crystalloid solution targeting dynamic measures, starting antimicrobials within 1 hour of sepsis recognition, and early initiation of vasopressors.[35] Norepinephrine is first line, associated with decreased mortality and less volume resuscitation needs, followed by vasopressin.[104]

Nosocomial Infections

Ventilator-Associated Pneumonia

As discussed earlier in the section on the respiratory system, VAP is defined as a pulmonary parenchymal infection after 2 days of mechanical ventilation. Although ICU patients with VAP have high mortality, it is hard to evaluate whether the presence of a VAP is an independent predictor of mortality or, rather, a sign of overall illness and morbidity. Early-onset pneumonia is typically associated with oropharyngeal flora, and late-onset pneumonia is associated with multidrug-resistant pathogens.[105] Criteria for the diagnosis of VAP are >2 days of mechanical ventilation, worsening oxygenation, purulent secretions, and a positive culture. VAP-prevention bundles are considered the standard of care and include direct preventative measures such as head-of-bed elevation to 30 to 45 degrees, daily sedation holidays, daily spontaneous breathing trials, oral chlorhexidine wash, and subglottic suctioning. Indirect measures include peptic ulcer prophylaxis and DVT prophylaxis.[106] Implementation of VAP bundles has been shown to decrease VAP rates, reduce mortality, and reduce overall hospital costs.[107,108] Treatment for VAP is typically 1 week of antibiotic therapy, which has been shown to have comparable outcomes to the prior typical 14-day course.[109]

Central Line–Associated Bloodstream Infections

A central line–associated bloodstream infection (CLABSI) is defined as a confirmed bloodstream infection in a patient with a central line, without another source for the infection. CLABSIs occur because skin flora travels along the catheter and colonizes the catheter, making its way into the bloodstream. Tunneled catheters have a cuff that creates a barrier to bacterial migration, which makes them less prone to infection. CLABSI is associated with a 15% mortality rate.[110] This is why prevention strategies are so important and have been effective at reducing the overall rate of CLABSI around the country. Prevention strategies include aseptic technique during insertion (hand hygiene, chlorhexidine for skin preparation, and sterile draping), choice of catheter site (in order of infection risk: femoral vein > internal jugular vein > subclavian vein), the use of antibiotic-impregnated catheters, early definitive catheter removal (scheduled replacement of catheters does not reduce the CLABSI risk), and chlorhexidine-impregnated dressings.[111] Treatment includes antibiotics and prompt removal of the catheter. Catheter salvage is only acceptable in patients with very limited access sites or in the setting of long-term catheters. In these cases, antimicrobial locks are used to preserve catheters while being treated for the infection. Antibiotic duration is dependent on the organism isolated.

Catheter-Associated Urinary Tract Infection

A *catheter-associated urinary tract infection* (CAUTI) is defined as a urinary tract infection in a patient with a urinary catheter or in the setting of catheterization in the prior 48 hours. CAUTIs are the most common nosocomial infection, with the main risk factor being the duration of catheter therapy. Catheters carry risk because they provide a direct path for pathogens from the rectal flora or ambient environment to travel to the bladder, allow bacteria to bypass the urethral sphincters, eliminate the protective turbulence associated with natural voiding, and cause trauma to the urothelium that makes it susceptible to bacterial colonization and entry.[112] Prevention involves removing the catheter as soon as it is no longer necessary and the use of aseptic technique during placement. There is also a suggestion in the literature that intermittent catheterization is better than indwelling catheters in certain populations, specifically in patients with spinal cord injuries.[113] Diagnosis is made by urinalysis and urine culture, which should only be sent in the setting of symptoms. Symptoms include typical infectious symptoms, such as fevers, rigors, and malaise, and more specific urinary symptoms, such as dysuria and pain, although these are hard to assess in patients with catheters. A CAUTI is diagnosed when the urinalysis reveals either $\geq 10^3$ colony-forming units/mL based on the Infectious Diseases Society of America guidelines or $\geq 10^5$ colony-forming units/mL based on the Centers for Disease Control and Prevention guidelines. The presence of pyuria, or white blood cells in the urine, in patients with a urinary catheter does not differentiate between a CAUTI and asymptomatic bacteriuria. However, the absence of pyuria makes CAUTI highly unlikely. Treatment includes removal or exchange of the urinary catheter, typically before initiating antibiotic therapy, and antibiotics. Antibiotic duration can range from 7 days for patients who are prompt responders to 14 days in delayed responders.

Clostridioides difficile

C. difficile is a gram-positive anaerobic organism that proliferates in the bowel when the microbiome is altered, particularly during and after antibiotic use. It is transmitted via the fecal-oral route and, in the hospital setting, typically spread via hospital personnel. *C. difficile* releases toxins that lead to inflammation of the bowel wall and create raised mucosal plaques called *pseudomembranes.* This is usually only seen in severe disease. Risk factors for a *C. difficile* infection include antibiotic exposure, hospitalization, and gastric acid suppression (e.g., PPIs). The primary symptom is watery diarrhea, which can develop, as the disease progresses, into shock, multiorgan failure, and toxic megacolon, noted by a very dilated colon on imaging. Diagnosis is made by sending a stool sample. Most institutions test for both the presence of the bacteria in the stool and the presence of the cytotoxin.

C. difficile infection is categorized into three severity levels: *nonsevere disease,* defined as white blood cell count <15,000 cells/mL and creatinine <1.5 mg/dL; *severe disease,* defined as white blood cell count ≥15,000 cells/mL and creatinine >1.5 mg/dL; or *fulminant disease,* defined as hemodynamic shock or megacolon. Treatment begins with the initiation of antibiotics, either oral vancomycin or oral fidaxomicin. In the setting of a severe infection or in the case of an ileus, intravenous metronidazole or rectal vancomycin may be added. Antibiotic treatment is usually continued for 10 to 14 days. Recurrent episodes can be treated with the same antibiotics but may require a longer duration. Chronic colonizers with recurrent infections may require oral vancomycin prophylaxis while on other antibiotics. For recurrent disease, a fecal transplant can also be considered, which has proven to change the microbiome of the colon and may decrease the risk of recurrent infection.[114] Indications for surgery during an acute infection include peritonitis, worsening hemodynamic shock, perforation, or toxic megacolon. Delaying surgery in the setting of shock can increase mortality. Surgical options include a subtotal colectomy, current standard of care, and for select patients without perforation or peritonitis, a loop ileostomy with colonic lavage and antegrade vancomycin enemas.[115,116] The original procedure was described as initially performing a diagnostic laparoscopy to assess for colonic viability, then creating a loop ileostomy and infusing 8 L of warmed polyethylene glycol 3350/electrolyte solution into the colon, with postoperative antegrade vancomycin flushes (500 mg in 500 cc of lactated Ringer solution every 8 hours over 10 days) through a Malecot catheter into the distal limb of the ileostomy.[116] The original study and other small cohort studies have shown that this method reduces mortality and increases colonic preservation.[115,116]

PALLIATIVE CARE AND END OF LIFE

As the population ages and our abilities to extend life in the ICU improve, the incorporation of palliative care is a crucial skill set for the surgical intensivist. Palliative care is the patient- and family-centered approach focused on the alleviation of symptoms. This includes pain management and psychosocial support. Its integration into ICU care is critical.

It is imperative to understand that the term *palliative care,* although often inclusive of end-of-life care, is *not* synonymous with *withdrawal of care.* This is a common misconception, particularly among surgeons, and may lead to hesitation to involve a palliative care team early in a patient's course. Elderly, frail, and comorbid patients, in particular, may benefit from early engagement of a palliative care team.[117]

Recent literature suggests that surgeons often struggle to provide appropriate guidance to patients with severe surgical problems in the preoperative period.[118] Despite efforts to improve such preoperative deliberation,[119] insurmountable complications occur, and patients and their families may find themselves in the surgical ICU facing unexpected death. If this situation occurs, it is important for the surgeon and critical care physician to recognize impending death and address it in a frank and transparent manner with the patient and family.

Although these discussions are difficult and nuanced, if performed well, the patient's family and care team can often come to a resolution that has the patient's best interest in mind. Engaging local experts, including palliative care specialists and the hospital's ethics committee, can be quite beneficial and is recommended. Critical care physicians are an integral part of such processes.

Devlin JW, Skrobik Y, Gélinas C, et al. Clinical practice guidelines for the prevention and management of pain, agitation/sedation, delirium, immobility, and sleep disruption in adult patients in the ICU. *Crit Care Med.* 2018;46(9):e825-e873.

This most recent clinical practice guideline developed via the Society of Critical Care Medicine offers the most recent summary of supporting recommendations and associated literature gaps in the assessment, prevention, and treatment of pain, agitation/sedation, delirium, immobility (mobilization/rehabilitation), and sleep (disruption) in critically ill adults.

Girard TD, Exline MC, Carson SS, et al. Haloperidol and ziprasidone for treatment of delirium in critical illness. *N Engl J Med.* 2018;379(26):2506-2516.

In a multicenter randomized double-blind placebo-controlled trial of critically ill patients, haloperidol (typical antipsychotic) or ziprasidone (atypical antipsychotic), as compared with placebo, did not significantly alter the duration of delirium, survival, time to freedom from mechanical ventilation, or time to ICU and hospital discharge.

PEPTIC Investigators for the Australian and New Zealand Intensive Care Society Clinical Trials Group, Alberta Health Services Critical Care Strategic Clinical Network, Irish Critical Care Trials Group, et al. Effect of stress ulcer prophylaxis with proton pump inhibitors vs histamine-2 receptor blockers on in-hospital mortality among ICU patients receiving invasive mechanical ventilation: the PEPTIC randomized clinical trial. *JAMA.* 2020;323(7):616-626.

In this multicenter, five-country, cluster crossover randomized clinical trial, ICU stress ulcer prophylaxis with PPIs versus histamine-2 receptor blockers did not alter all-cause mortality (primary end point), upper GI bleeding, C. difficile *infection, or ICU and hospital lengths of stay.*

Singer M, Deutschman CS, Seymour CW, et al. The Third International Consensus definitions for sepsis and septic shock (Sepsis-3). *JAMA.* 2016;315(8):801-810.

This seminal work updates the definitions for sepsis and septic shock and facilitates earlier recognition and more timely management using these standardized metrics.

STARRT-AKI Investigators, Canadian Critical Care Trials Group, Australian and New Zealand Intensive Care Society Clinical Trials Group, et al. Timing of initiation of renal-replacement therapy in acute kidney injury. *N Engl J Med.* 2020;383(3):240-251.

In this multinational randomized controlled trial of ICU patients with AKI, an accelerated strategy of RRT within 12 hours of meeting eligibility, compared with a standard strategy, was not associated with lower 90-day mortality and was possibly associated with more adverse events and dependence on RRT at 90 days.

Venkatesh B, Finfer S, Cohen J, et al. Adjunctive glucocorticoid therapy in patients with septic shock. *N Engl J Med*. 2018; 378(9):797-808.

In this multicenter randomized clinical trial, among patients with septic shock undergoing mechanical ventilation, a continuous infusion of hydrocortisone (200 mg/day) did not alter 90-day mortality more than placebo, but it shortened resolution of shock.

CHAPTER 47

Moving Operating Room Procedures to the Intensive Care Unit

Bradley M. Dennis, Rachel D. Appelbaum, and Jose J. Diaz

OUTLINE

Rationale for Bedside Surgical Procedures
Taking the Operating Room to the Bedside
Safety Practices for Bedside Surgical Procedures
Selection of Patients for Bedside Surgical Procedures
Laparotomy and the Open Abdomen
Tracheostomy
Percutaneous Endoscopic Feeding Tubes
Bronchoscopy
Summary

Bedside surgical procedures have become a standard in many intensive care units (ICUs), replacing the operating room (OR) as the preferred location for select procedures in critically ill patients.[1] Performing appropriately selected procedures within the ICU limits the risk of transporting critically ill patients, facilitates flexibility in timing and scheduling, decompresses busy ORs, and reduces cost.[2-4] The ability to perform some operations at the bedside may be lifesaving in critically ill patients too unstable to transport safely to the OR. Advancements in monitoring and sedation, endoscopic and percutaneous techniques, and bedside imaging have enabled the transition of several procedures traditionally performed in the OR, endoscopy, and interventional radiology suites to the ICU. Procedures now regularly performed in the ICU include bedside laparotomy, tracheostomy, percutaneous endoscopic feeding access, percutaneous drainage procedures, placement of inferior vena cava filters, and initiation of extracorporeal circulatory life support (the latter covered in a separate chapter). In the unstable patient, other procedures may be performed at the bedside, including irrigation and debridement of wounds, orthopedic stabilization with external fixation, fasciotomies, amputations, and diagnostic laparoscopy.

Although bedside operative procedures can be performed safely, with complication rates equal to those in the OR, doing so mandates that cases are appropriately selected and that appropriate safety practices are consistently implemented. The ICU represents a complex environment in which to perform complex processes and procedures. Recognition of the numerous potentials for error and adverse events in such settings is important. Based on the experience of industry and other high-reliability organizations, prevention of error and adverse events requires standardization of processes and elimination of variability.[5] Protocols and safety practices specifically for bedside operative procedures should be in place to ensure the ability to perform these procedures safely, with low infection rates, and with the assurance of comfort and amnesia. In this chapter, we discuss the following topics: (1) the rationale for bedside surgical procedures; (2) the process of bringing the OR to the bedside; (3) systematic safety methodologies and practices to ensure safe performance of bedside procedures; (4) selection of patients for bedside surgical procedures; and (5) specific considerations for common bedside procedures, such as bedside laparotomy, tracheostomy, percutaneous endoscopic feeding tubes, and bronchoscopy.

RATIONALE FOR BEDSIDE SURGICAL PROCEDURES

For good reasons, most surgical procedures are performed in the OR. The centralization of resources—including anesthesia personnel and equipment, surgical equipment, radiology, and specialized nursing and procedural support staff—and safety policies and principles make the modern surgical suite an ideal venue for most operations (Fig. 47.1). However, OR demand may exceed available resources, complicating timely access to the OR and scheduling of unplanned, urgent, or emergent cases. Competition for OR space may delay or prevent timely operative procedures for critically ill patients. Additionally, performance of procedures in the OR requires transportation of critically ill patients from the ICU and back, resulting in substantial resource use and costs. As the complexity and severity of illness of critical care patients have increased, so, too, have the risks related to their transport. The transport of critically ill patients frequently requires multiple personnel, including nursing staff, transport staff, respiratory care, and anesthesia staff. Furthermore, the change of venue and personnel caring for the patient necessitates detailed communication for handoff and transitions of care, representing a potential source of medical error. Consideration of transport to the OR should be evaluated in the same manner as other treatments by assessing risk versus benefit for the individual patient.[6] Each hospital should have guidelines for the inter- and intrahospital transport of critically ill patients to various parts of the hospital for imaging, tests, or procedures and to the OR to decrease this inherent risk.[7]

TAKING THE OPERATING ROOM TO THE BEDSIDE

Although the vast majority of surgical procedures should be performed in the OR, the ICU is a logical alternative location for some surgical procedures. The two locations are similar in many

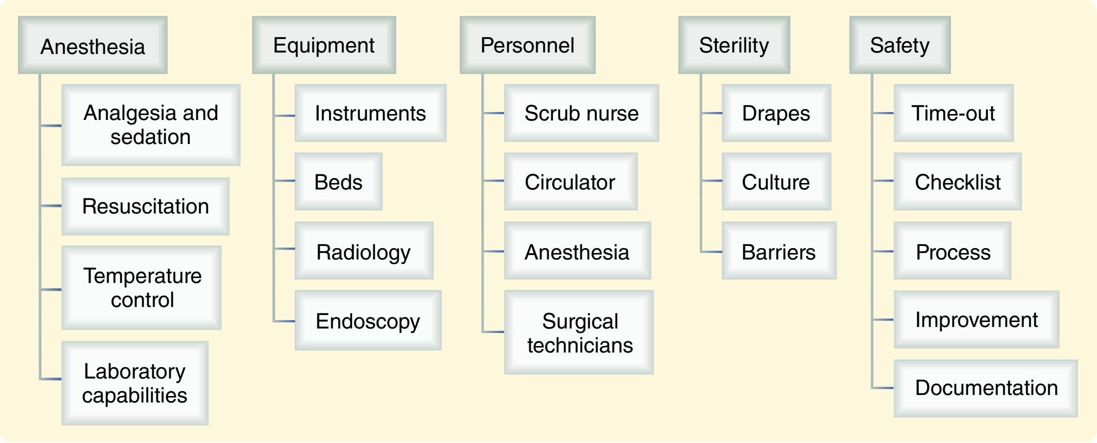

FIGURE 47.1 Resources available in the operating room.

ways. Both locations have equipment capable of real-time monitoring of cardiovascular, respiratory, and neurologic systems. The ICU and OR both have mechanical ventilation capability. In fact, many ICUs have ventilators with more advanced functionalities than their corresponding ORs. Although ICUs lack inhalational anesthetic administration capabilities, intravenous sedation and analgesia can be administered in the ICU to allow for the performance of bedside procedures. Lastly, and most importantly, there are analogous staff in the ICU. The roles of circulating OR nurses and anesthesia providers can be filled by the ICU team, which consists of a critical care nurse, respiratory therapist, and intensivist. The one crucial OR role not easily translated to the ICU setting is the scrub nurse or technician. Dedicated procedure support personnel have been described in the ICU setting to bridge this gap.[2] In this role, the procedure support nurse is responsible for many of the same functions as the scrub nurse. Dedicated procedure support personnel not only decrease the variability in how an individual procedure is performed, but they also play important roles in compliance with guidelines, both of which are significant factors in reducing error.

Multiple factors are required to create and maintain a successful system for performing bedside procedures (Fig. 47.2). Management guidelines may include standard operating procedures; preprocedure checklists, including time-out procedures; and sedation protocols. Appropriate access to supplies may require temporary storage of core equipment in an individual ICU with standardized restocking mechanisms, streamlining the supply chain. Finally, a facilitative mindset among staff is vital to the success of such a system.

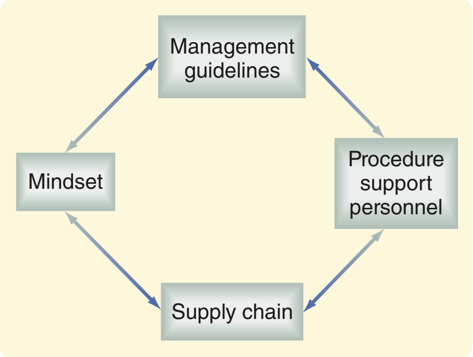

FIGURE 47.2 Fundamentals vital to the success of bedside surgical procedures.

SAFETY PRACTICES FOR BEDSIDE SURGICAL PROCEDURES

To ensure the safety of operative procedures performed at the bedside in the ICU, systematic measures should be in place for appropriate patient selection; adequate expertise of supporting personnel; limited procedural variability; adequate monitoring and anesthesia; and facilitation of concise, accurate, and specific intrateam communication. Measures shown to increase safety in the OR are also appropriate for procedures performed at bedside in the ICU. Implementation of the Safe Surgery Saves Lives program developed by the World Health Organization (WHO) has been associated with a significant global reduction in perioperative morbidity and mortality.[8] The 10 safety objectives outlined in the WHO Guidelines for Safe Surgery 2009 are as follows[9]:

1. The team will operate on the correct patient at the correct site.
2. The team will use methods known to prevent harm from administration of anesthetics while protecting the patient from pain.
3. The team will recognize and effectively prepare for life-threatening loss of airway or respiratory function.
4. The team will recognize and effectively prepare for the risk of high blood loss.
5. The team will avoid inducing an allergic or adverse drug reaction for which the patient is known to be at significant risk.
6. The team will consistently use methods known to minimize the risk for surgical site infection.
7. The team will prevent inadvertent retention of instruments and sponges in surgical wounds.
8. The team will secure and accurately identify all surgical specimens.
9. The team will effectively communicate and exchange critical information for the safe conduct of the operation.
10. Hospitals and public health systems will establish routine surveillance of surgical capacity, volume, and results.

The use of specifically trained procedure support personnel to support bedside operative procedures within the ICU greatly facilitates reduction in variability, compliance with standard operative procedures, reduction of communication errors, and maintenance of appropriate skill sets. Depending on the volume of procedures to be supported, these personnel can be dedicated to a specific unit or service or used to support bedside procedures on numerous services in multiple ICUs. Limiting this procedure support role to a small number of personnel allows a greater degree of expertise to be developed and is extremely valuable in maintaining procedural safety; this is particularly true with managing the airway and endotracheal tube during percutaneous tracheostomies. Additionally, these individuals are charged with the development and monitoring of safety practices and ensuring their application during all procedures.

Management guidelines, protocols, and standard operating procedures should be in place before the routine performance of bedside operative procedures. They should be in line with procedures developed for the OR and be easily accessible, and compliance should be monitored. Because of variations in specific personnel and practice patterns in various ICUs, documents may be customized to each location to ensure their appropriate application during bedside operative procedures. These documents should address the selection of appropriate cases, mandatory personnel, equipment, medications, and monitoring. An example of a bedside operative guideline is provided in Box 47.1.[3] All patients should have blood pressure, electrocardiography, pulse oximetry, end-tidal carbon dioxide, and ventilation routinely monitored throughout the procedures. Adequate personnel must be present to allow performance of the procedure, monitoring of sedation and anesthesia, medication administration, manipulation of ventilation if required, and documentation. The actual number of personnel required varies depending on the procedure and expertise of particular personnel. Analgesia and sedation must be ensured with appropriate medications under the direction of adequately credentialed personnel. Additionally, guidelines and protocols should include standards for adequate preparation, equipment, and instrument accounting.

The use of preprocedure time-outs and procedural checklists aid in ensuring appropriate safety practices. The use of these tools helps limit communication errors, facilitates compliance with standard operating procedures, and can aid in documentation and compliance monitoring. These tools should be consistent with practices employed in the OR to reduce variability where appropriate. Fig. 47.3 provides an example of such a procedural checklist. Ideally, these tools can be combined with forms required for documentation, and information can be captured for quality and performance analysis.

Ensuring a high degree of safety of bedside operative procedures and providing documentation of such when required mandate that mechanisms for tracking procedure performance, compliance monitoring, and adverse event review and reporting are developed. These mechanisms must be applicable locally to facilitate consistent, nonvariable performance and interface with global hospital safety mechanisms and initiatives. Development of process-mapping flow charts and diagrams facilitates the integration of unit-specific, departmental, and hospital-wide processes and helps delineate lines of communication and authority.

SELECTION OF PATIENTS FOR BEDSIDE SURGICAL PROCEDURES

As noted previously, if selected appropriately, bedside operative procedures can be performed with a similar risk of complications as when performed in the OR, at lower cost, and without transportation risks.[3,4] However, there are no randomized studies and few retrospective reviews that evaluate the safety of bedside operative procedures or help delineate what the appropriate patient populations and operative procedures are. The safety and efficacy of bedside procedures vary depending on the local experience and application of safety practices. As experience is gained, indications may broaden, and frequency may increase. The decision to perform an operative procedure at the bedside requires a careful risk-benefit analysis. This decision considers the difficulty and risk of transport; the complexity of the operation; the ability to achieve timely OR space; and the safety, ease, and cost savings of performing the procedure at the bedside. Most major operative procedures should be performed in the OR. In general, the indications for bedside operative procedures fall into two categories: (1) the patient requires a lifesaving intervention but is too unstable for transport to the OR and (2) low-complexity procedures in which the risk of transport, difficulties of OR scheduling, and cost and resource use of the OR favor a bedside procedure. Factors that generally favor performance of procedures in the OR include

BOX 47.1 Bedside Surgery Protocol

Indications

- Decompressive celiotomy for abdominal compartment syndrome
- Exploratory celiotomy for intraabdominal hemorrhage after damage control and packing
- Reexploration of a previously open abdomen for washout or closure
- Exploratory celiotomy to rule out intraabdominal sepsis in a patient with ventilatory requirements that prohibit safe transport to the operating room (OR)

Protocol

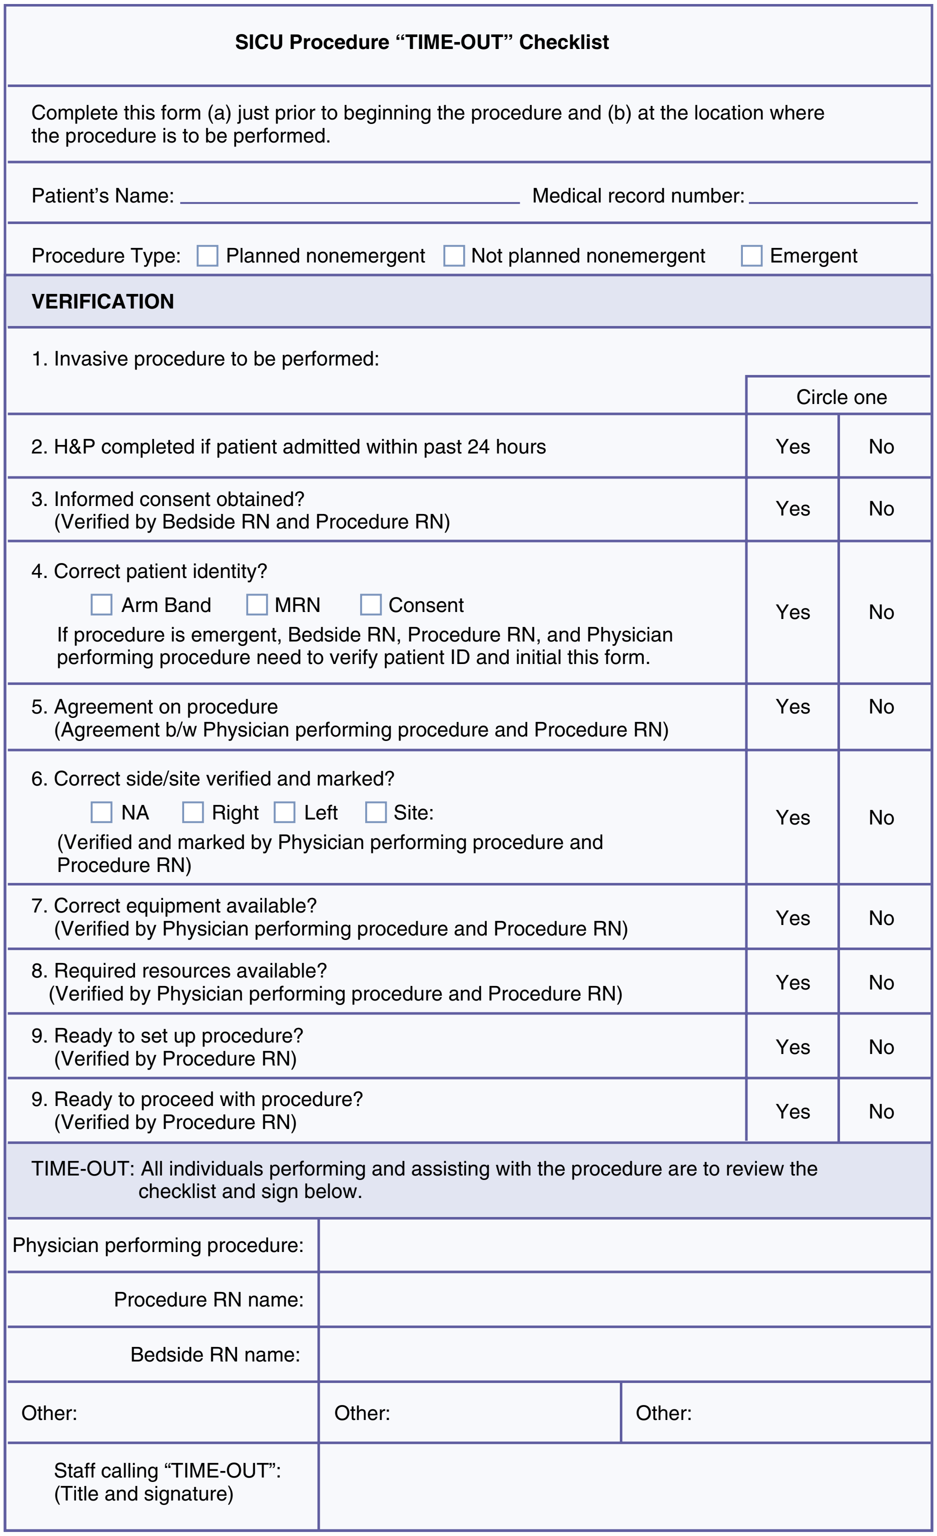
a. Intensive care unit (ICU) attending physician and operating surgeon will be present for the entire surgical procedure.
b. Informed consent will be obtained (if possible).
c. Preprocedure checklist will be reviewed by the bedside nurse.
d. Bedside nurse and a respiratory therapist will monitor patient and record procedure (conscious sedation sheet).

Indications to proceed to OR:

- Surgical bleeding
- Dead bowel
- Need to open another body cavity
- Surgeon preference

For laparotomies:

- A sterile perimeter will be set up in the patient's room. All individuals must wear a surgical head covering and mask.
- The ICU attending physician will oversee anesthetic management of the patient.
- General anesthesia will include narcotics, benzodiazepines, propofol, paralytics, and ventilator management.
- A sterile hand wash will be performed by the operating team.
- Preoperative antibiotics are indicated only if a new surgical wound is to be made (e.g., cefazolin [Ancef], 1–2 g intravenously).
- A povidone-iodine (Betadine)–chlorhexidine abdominal preparation will be used.
- A standard Bovie will be set up (when indicated).
- Wall suction canisters will be set up.
- A 4-L warm irrigation with normal saline will be used.
- A standard bedside celiotomy tray will be set up with suture on a sterile field.



SICU Procedure "TIME-OUT" Checklist

Complete this form (a) just prior to beginning the procedure and (b) at the location where the procedure is to be performed.

Patient's Name: ______________________ Medical record number: ____________

Procedure Type: ☐ Planned nonemergent ☐ Not planned nonemergent ☐ Emergent

VERIFICATION

1. Invasive procedure to be performed:

	Circle one	
2. H&P completed if patient admitted within past 24 hours	Yes	No
3. Informed consent obtained? (Verified by Bedside RN and Procedure RN)	Yes	No
4. Correct patient identity? ☐ Arm Band ☐ MRN ☐ Consent If procedure is emergent, Bedside RN, Procedure RN, and Physician performing procedure need to verify patient ID and initial this form.	Yes	No
5. Agreement on procedure (Agreement b/w Physician performing procedure and Procedure RN)	Yes	No
6. Correct side/site verified and marked? ☐ NA ☐ Right ☐ Left ☐ Site: (Verified and marked by Physician performing procedure and Procedure RN)	Yes	No
7. Correct equipment available? (Verified by Physician performing procedure and Procedure RN)	Yes	No
8. Required resources available? (Verified by Physician performing procedure and Procedure RN)	Yes	No
9. Ready to set up procedure? (Verified by Procedure RN)	Yes	No
9. Ready to proceed with procedure? (Verified by Procedure RN)	Yes	No

TIME-OUT: All individuals performing and assisting with the procedure are to review the checklist and sign below.

Physician performing procedure:		
Procedure RN name:		
Bedside RN name:		
Other:	Other:	Other:
Staff calling "TIME-OUT": (Title and signature)

complex procedures, complex or extensive equipment needs, risk of encountering significant bleeding, need for insertion of prosthetic materials, significant lighting requirements, and lengthy procedures. Commonly performed bedside procedures in the ICU include percutaneous and open tracheostomy, percutaneous endoscopic gastrostomy (PEG) or percutaneous endoscopic transgastric jejunostomy (PEGJ) tube placement, bronchoscopy, soft tissue debridement, decompressive laparotomy for abdominal hypertension, washout and packing removal after a damage control laparotomy, placement of inferior vena cava filters, and damage control orthopedic procedures (e.g., placement of external fixator). Occasionally, the condition of extremely critically ill patients can be temporized at the bedside by the performance of an operative procedure in the ICU with subsequent performance of the definitive operation in the OR.

LAPAROTOMY AND THE OPEN ABDOMEN

Laparotomy at the bedside in the ICU was initially a procedure of last resort in patients too sick to proceed to the OR—a heroic attempt to identify reversible intraabdominal pathology because the patient was near death.[3] However, the recognition of abdominal compartment syndrome (ACS) as a frequent complication of fluid resuscitation in acutely ill patients resulted in the acceptance of the "damage control" approach to the management of acutely ill patients with intraabdominal pathology. Historically, this led to an increase in the application of bedside laparotomy in the controlled settings of the ICU, although the incidence of this is decreasing in the United States with current-era resuscitation practices liberally using blood instead of fluid. Damage control and management of ACS use an open abdomen approach in which the fascia remains open, which necessitates the use of various temporary abdominal closure techniques. Indications for bedside laparotomy can be classified as emergent or semielective. Common emergent indications include (1) decompressive laparotomy for ACS, (2) control and packing for recurrent bleeding after a previous damage control laparotomy, and (3) suspicion of intraabdominal infection in patients too critically ill to be transported to the OR. Common semielective indications include (1) pack removal after damage control laparotomy, (2) irrigation and debridement of the open abdomen, (3) source control and surveillance for sepsis resulting from intraabdominal pathology, and (4) management of traumatic abdominal defects.

Historically, the most common emergent indication for ICU laparotomy was for decompression of abdominal hypertension. Recognition and understanding of the pathophysiology of increased intraabdominal pressure leading to organ system dysfunction—ACS—have increased significantly since first described as the measurement of intraabdominal pressure as an indication for abdominal reexploration. ACS can be classified as primary, resulting from intraabdominal processes, or secondary, resulting from bowel edema and intraabdominal fluid due to the treatment and resuscitation of extraabdominal pathology. Increasing intraabdominal pressure leads to alterations in abdominal perfusion pressure, restricted venous return, and reduction of pulmonary compliance. These alterations can lead to cardiac failure, pulmonary decompensation, and oliguria. Severe elevations in abdominal pressure can lead to organ hypoperfusion and ischemia, although the pressure at which this occurs may vary depending on mean arterial pressure. Grading systems for the degree of abdominal hypertension have been proposed, with grades III (21–25 mm Hg) and IV (>25 mm Hg) considered to be significantly elevated, and when coupled with new-onset organ dysfunction, this defines ACS.[10] Management of ACS involves measures to ensure adequate abdominal perfusion at lower pressures, but as intraabdominal pressure increases, abdominal decompression by laparotomy is indicated. Appropriate treatment requires recognition of the development of this syndrome.

The indirect measurement of bladder pressures via intravesicular catheter has become the gold standard because of its widespread availability and limited invasiveness. This technique is performed by clamping and attaching the drainage tubing of the Foley to a three-way stop, zeroing the system, and then injecting 25 mL of sterile saline into the bladder. Bladder pressures over 25 mm Hg are highly suspicious for ACS, but the intensivist must take the entire clinical picture into account. Bladder pressure measurements are contraindicated in bladder trauma, neurogenic bladder, and pelvic hematoma. It is important to note that bladder pressures will be potentially inaccurate if the patient is not completely sedated or lying flat.

The acceptance of damage control, an abbreviated laparotomy to salvage trauma patients with exsanguination, has led to an application of bedside laparotomy for control of recurrent bleeding within the abdomen before correction of the patient's systemic physiology and for removal of abdominal packs, irrigation, and debridement. Bedside laparotomy in the ICU is common in most major US academic and trauma centers where damage control and temporary abdominal closure for patients in extremis are frequently used. Numerous methods of temporary abdominal closure have been described and continue to evolve. In 2022, the Eastern Association for the Surgery of Trauma published a practice management guideline regarding techniques to manage the open abdomen. This systematic review and meta-analysis conditionally recommends the use of a fascial traction system over routine care when treating patients with an open abdomen after damage control laparotomy. This recommendation is based on the benefit of improved primary myofascial closure without worsening mortality or enterocutaneous fistula formation.[11]

The open abdominal approach is also applied to the general surgery population, most commonly for the management of abdominal sepsis with bowel edema and the inability to perform a fascial closure, hemodynamically unstable patients requiring damage control procedures, necrotizing soft tissue infection of the abdominal wall, diffuse peritonitis in patients at high risk of failure of source control, and mesenteric ischemia.[3] Damage control techniques with staged gastrointestinal reconstruction, serial abdominal washouts for source control, and delayed abdominal wall closure can be used in the management of these very complex patients. Controlled trials of these techniques are limited, and the indications and settings in which the open abdominal approach is most appropriate are not fully determined.

Surgical rescue of the critically ill patient has become an increasing area of awareness. In select critically ill patients with severe cardiopulmonary instability precluding transport to the OR, a resuscitative bedside laparotomy in the ICU may be indicated. Patients who require an emergent bedside laparotomy have an extremely high rate of death, with over 50% mortality. This information may be useful in the setting of preintervention counseling with patients' families.[12]

TRACHEOSTOMY

Tracheostomy is the most common surgical procedure in critically ill patients requiring prolonged mechanical ventilation.[13] Table 47.1 shows some of the common indications and contraindications for tracheostomy. Nearly all contraindications are relative ones, and most are temporary. Indications for tracheostomy in critically ill patients fall broadly into three categories: (1) upper airway obstruction, (2) prolonged mechanical ventilation, and (3) neurologic condition preventing safe extubation.

The ease and convenience of bedside tracheostomy in critically ill patients have made performance at the bedside the standard in many institutions. Open and percutaneous dilatational tracheostomy (PDT) can be performed safely at the bedside in the ICU.[2,14] Conversion from Jackson endotracheal tube size to tracheostomy size is shown in Table 47.2. Evidence-based guidelines

TABLE 47.1 Indications and Contraindications for Tracheostomy

INDICATIONS	CONTRAINDICATIONS
Upper airway obstruction	Recent anterior neck surgery (<7 days)
Difficult airway	High ventilator settings
Significant maxillofacial trauma	Fraction of inspired oxygen >50%
Angioedema	Positive end-expiratory pressure >10 cm H_2O
Upper airway tumors	Advanced ventilator modes
Neurologic condition preventing safe extubation	Elevated intracranial pressure
Brain injury—acute or progressive	Hemodynamic instability
Spinal cord injury (including halo fixation)	Significant bleeding risk
Severe agitation or delirium	Local infection or malignancy at proposed site
Prolonged altered mental status	Predicted early mortality
Prolonged mechanical ventilation	

do not recommend one specific technique over another with respect to reducing complications or mortality.[15] PDT has become widely used for elective tracheostomy in critically ill adult patients. Ciaglia and colleagues[16] first described elective PDT in 1985, and since that time, numerous modifications to the technique have been made. When comparing PDT with standard surgical tracheostomy performed in the OR via systematic review and meta-analysis, PDT suggested decreased wound infection and clinically relevant bleeding.[14] Percutaneous tracheostomy has also been demonstrated to be more cost-effective in critically ill ICU patients.[17] Periprocedural mortality related to PDT in randomized studies appears to be less than 0.2%.[2,14] The safety of bedside PDT was described in a single institutional retrospective analysis of more than 3000 consecutive procedures.[2] This case series revealed a periprocedural major complication rate of 0.15% and a periprocedural mortality rate of less than 0.1% within this population of critically ill patients. Additionally, this work demonstrated the safety of bedside PDT in patients of higher obesity classes. These data are useful for decisions regarding the indications for tracheostomy in critically ill patients; patients should be considered for tracheostomy when the risks of failure of extubation or airway loss resulting in death are estimated to be less than 1 in 1000.

Timing of tracheostomy is controversial in patients with predicted prolonged mechanical ventilation.[18] Most studies have shown no difference in relevant clinical outcomes such as mortality, pneumonia rates, and hospital length of stay.[17-19] Studies have supported early tracheostomy (up to 7 days) versus delayed tracheostomy (after 7 days), with shorter ICU stays and less mechanical ventilation but with no difference in mortality in trauma and nontrauma populations.[19-23] However, a randomized study of medical ICU patients demonstrated a significant reduction in mortality (32% vs. 62%), pneumonia (5% vs. 25%), and accidental extubation (0 vs. 6) when early tracheostomy at 48 hours was compared with delayed tracheostomy at 14 to 16 days for patients predicted to require more than 2 weeks of mechanical ventilation.[24] The early group also had significantly decreased ICU length of stay and ventilator days. The largest randomized clinical trial studied >900 adult patients enrolled in 72 ICUs across 13 academic and 59 nonacademic UK hospitals, where early (within 4 days) was compared with late (after 10 days) tracheostomy. From a follow-up period of 30 days to 2 years, there was no mortality difference,[20] which is supported by a number of recent systematic reviews.[25,26] Notably, in this British trial, over 50% of those randomized to late tracheostomy did not require a tracheostomy due to liberation from mechanical ventilation and/or ICU discharge.[20]

TABLE 47.2 Conversion from Jackson Endotracheal Tube Size to Tracheostomy Size

JACKSON SIZE	INNER DIAMETER WITH INNER CANNULA (MM)	INNER DIAMETER WITHOUT INNER CANNULA (MM)	OUTER DIAMETER (mm)
4	5.0	6.7	9.4
6	6.4	8.1	10.8
8	7.6	9.1	12.2
10	8.9	10.7	13.8

The COVID pandemic presented new challenges to the bedside percutaneous tracheostomy. Because it is an aerosol-generating procedure, appropriate airborne and droplet precautions are required for proceduralist and procedural support personnel if the patient is still actively shedding virus. Appropriate timing of the procedure is a topic of some debate. Retrospective data and meta-analysis suggest that tracheostomy after 10 to 14 days of mechanical ventilation is associated with a lower duration of mechanical ventilation and ICU length of stay without increases in mortality.[27,28] In addition, the pandemic brought to the forefront the practice of tracheostomy in patients on extracorporeal membrane oxygenation (ECMO). Tracheostomy can be safely performed in this group at the bedside with appropriate hemostatic technique. Complications are higher overall, almost entirely related to bleeding, but percutaneous and open techniques showed no difference in complication rate.[29]

Reported perioperative complications of percutaneous tracheostomy include the following: peristomal bleeding from injury to the anterior jugular veins or thyroid isthmus, injury of the posterior trachea and/or esophagus by laceration through the back wall of the trachea, extraluminal placement by creating a false tract during placement of the tracheostomy tube, and loss of airway. Long-term complications have not been adequately studied in randomized trials to draw conclusions.

Major perioperative complications can be minimized by employing safety measures outlined in the previous sections. Using specifically trained support personnel to manage the airway is particularly helpful in limiting airway mishaps. Dedicated multidisciplinary tracheostomy teams have been shown to reduce time to decannulation, length of stay, and adverse events.[30] Additionally, one of two techniques should be used to ensure proper positioning of the tracheostomy tube and minimize risk of loss of airway by inadvertent extubation during the procedure: bronchoscopic guidance or a semiopen technique with blunt dissection to the anterior trachea. However, bronchoscopic guidance does not eliminate severe tracheal injuries, and involvement of experienced personnel is important to prevent these complications. Recently, the use of preprocedure ultrasound to identify the neck anatomy has been described as helpful in decreasing the potential risk of bleeding from crossing veins, identifying enlarged thyroid lobes, and decreasing the number of sticks.[31,32] This has been especially helpful with patients in the higher obesity classes. Long term, the incidence of serious tracheal stenosis after percutaneous tracheostomy is low, with reports of 6%,[33] and tracheal stenosis usually occurs early in the subglottic position. Subclinical tracheal stenosis is found in 40% of patients.[34] Follow-up of patients discharged from the ICU with tracheostomies is important to minimize and identify complications.

PERCUTANEOUS ENDOSCOPIC FEEDING TUBES

Gauderer and coworkers[35] first described PEG in 1980 for access into the stomach for enteral feedings using a "pull" technique. Various other techniques have since been described. The principle of a sutureless approximation of the stomach to the anterior abdominal wall has allowed the pull technique to become the most popular method used. The other two most commonly used techniques are the "push" and introducer techniques, both of which require the use of stay sutures to approximate the stomach to the anterior abdominal wall. Newer PEGJ tubes combine gastric and jejunal ports to allow distal feeding and proximal decompression.

Accepted primary indications for a PEG or PEGJ include inability to swallow, high risk of aspiration, severe facial trauma, and indications for mechanical ventilation for longer than 4 weeks.[36] Other indications include nutritional access for debilitated patients and patients with dementia with severe malnutrition. PEG tubes have been associated with reducing overall hospital costs.

Numerous gastrostomy and gastrojejunostomy tubes are commercially available. Most allow simple gastrostomy assessment with or without a valve. Some are flush with the skin and require a tube to be attached only during feeding. For critically ill patients with an increased risk of aspiration, multilumen PEGJ tubes are available. These tubes allow drainage of the stomach while feeding the proximal jejunum. A third lumen connects to a balloon that maintains apposition of the gastric and abdominal walls.

Enteral feeding through a newly placed percutaneous feeding tube can usually be initiated after 12 to 24 hours. Studies evaluating the efficacy of early initiation of enteral nutrition have demonstrated encouraging results; however, delayed feeding after percutaneous placement continues to be widely practiced. Dubagunta et al. performed a prospective study using a protocol standardizing enteral nutrition after 4 hours. They concluded that initiation of enteral feeding after PEG tube placement can be successfully completed with a systematic protocol and close observation. The protocol was safe and associated with significant cost savings by eliminating the need for inpatient hospitalization postprocedure.[37,38]

Contraindications for PEG placement include the following: no endoscopic access, significant ascites, severe coagulopathy, gastric outlet obstruction or previous gastric resection, gastric bypass surgery, survival of less than 4 weeks, inability to bring the gastric wall in approximation to the abdominal wall, and severe immunosuppression (white blood cell count <1). There are a few relative contraindications, such as an inability to transilluminate through the anterior abdominal wall, gastric varices, diffuse gastric cancer, and agitation requiring restraints. It may be nearly impossible to place a PEG in class III obese patients (body mass index >40 kg/m^2) because of the thickness of the abdominal wall. Anterior wall inflammation or infection should be treated before the procedure. If there are no other options, ascites may be drained before the procedure to facilitate PEG tube placement.[39] PEG tubes may be placed in the presence of a ventriculoperitoneal shunt or a dialysis catheter. However, placement should be separated by 1 to 2 weeks or more to minimize the risk of catheter infection.[40] History of a previous or recent laparotomy is not a contraindication for PEG. However, one may consider a preprocedure CT scan to confirm there is a clear window for PEG placement. A discrete indentation of the stomach when palpating the anterior abdominal wall and adequate transillumination should be ensured.[41]

PEG is thought to be a safe procedure whether it is performed in the gastrointestinal laboratory, the OR, or at bedside in the ICU. However, because PEG tube placement is frequently performed in debilitated or critically ill patients, complications are associated with a higher mortality than would be expected for most elective procedures.[42] Free intraperitoneal air after PEG is common and can persist for 4 weeks, although it should not be considered benign on initial evaluation.[43] Abdominal wall infection can occur as an early complication of PEG placement; an ample skin incision that prevents creation of a closed space around the feeding tube and administration of antibiotics before the procedure have been demonstrated to decrease PEG site infections.[44] Dislodgment of the PEG from the stomach can occur and may be life threatening. Dislodgment may occur acutely through the application of traction on the gastrostomy tube, pulling it partially or completely through the abdominal wall. Alternatively, the tube may necrose through the stomach wall if the internal PEG flange, disc, balloon, or bumper (i.e., buried bumper syndrome) applies too much pressure on the gastric wall. If this complication occurs before development of a fibrous tract during the initial 10 to 14 days, it should be considered a surgical emergency because gastric contents would spill into the abdominal cavity; operative closure of the gastrostomy is required. To minimize the risk of this complication, methods that prevent inadvertent movement of the gastrostomy tube should be used and meticulously followed. These methods include recording of the position of the gastrostomy tube at the skin surface immediately after the procedure with routine verification and application of binders or other devices that limit the inadvertent application of traction on the tube. Of note, the historical common practice of tube fixation to the external abdominal wall has been deemed a less critically important method, and it has even been abandoned at some major centers to limit external skin morbidities.

Patients requiring access for enteral nutrition are inherently at risk for healing issues due to malnutrition. Patients on high-dose steroids or chemotherapy present additional complexity to wound healing and are at increased risk for complications with feeding tube dislodgement. Hyperactive, delirious, or agitated patients are also at increased risk for tube complications; hence, they represent a relative contraindication for placement. As mentioned, the morbidity associated with early tube dislodgement is significant and often requires surgical exploration for gastric repair and tube replacement. Timratana et al. performed a small retrospective review of PEG placement when their group began to selectively place T-fasteners in high-risk agitated patients. They concluded the placement of T-fasteners may decrease overall morbidity if early tube dislodgement occurs and tubes can be nonemergently replaced.[45] Other institutions place nonremoval PEG tubes in these same populations, with a lower risk of dislodgement requiring laparotomy but higher rates of buried bumpers and soft tissue complications, along with the disadvantage of needing a second endoscopic procedure for PEG excision and removal when it is no longer required for enteral support.

BRONCHOSCOPY

Fiberoptic bronchoscopy of critical care patients is indicated for diagnostic and therapeutic purposes. Therapeutic indications include insertion of an endotracheal tube, removal of foreign bodies inadvertently aspirated, removal of mucous plugs, reversal of atelectasis in mechanically ventilated patients, suctioning of thick tenacious secretions, and diagnosis of obstructive pneumonia.[46]

Diagnostic bronchoscopy is most commonly used for obtaining pulmonary specimens for diagnosis and management of pneumonia.[47] Quantitative cultures obtained via fiberoptic bronchoscopy have been shown to eliminate the diagnosis of pneumonia in nearly 50% of patients with clinical signs of pneumonia, to decrease inappropriate antibiotic use, and to improve mortality compared with nonquantitative techniques. Standardization of culture techniques should be undertaken.

Currently, they exist as single-use flexible bronchoscopes (SFBs) or reusable flexible bronchoscopes (RFBs). Traditionally, RFBs have played a crucial role in the diagnosis and treatment of pulmonary diseases; however, they come with some limitations, including risk of cross-infection (2.8% risk), high maintenance cost, and long waiting times for decontamination.[48] In 2009, the Ambu company first invented an SFB. The greatest benefit of SFBs is the avoidance of cross-infection. Additionally, they are portable and easy to set up. They do not require endoscopy staff or a large bronchoscopy tower. Since its initial development, the SFB has been modified and improved, and it is used widely in clinical practice. The COVID-19 pandemic led to increased interest and use. Several studies have evaluated the efficacy of these bronchoscopes.[48] He et al. performed a prospective controlled study with 45 patients undergoing bronchoscopic biopsy. The authors concluded that SFBs are noninferior to RFBs in routine bronchoscopy, bronchoalveolar lavage, and biopsy.[49]

The risk associated with diagnostic bronchoscopy is related to the need for conscious sedation and the required medications if performed in a nonintubated patient. Medication use can possibly result in depressed mental status progressing to hypoventilation, airway vulnerability, and the risk of aspiration. The risks of the procedure itself are pneumothorax, hypoxia, airway hyperreactivity, pulmonary hemorrhage, loss of pulmonary reserve in patients on high ventilator settings, and systemic hypotension or hypertension.

SUMMARY

This chapter covered the rationale for bedside surgical procedures in the ICU, resources required, and safety practices and considerations for transitioning procedures from the OR to the ICU. Given the rising demand for OR resources in many healthcare systems, using the nimbler ICU environment with properly supported personnel and clear protocols can enhance throughput of patient care. With attention to patient selection, laparotomy for acute abdominal pathologies, tracheostomy, percutaneous endoscopic feeding access, and bronchoscopy have evolved into reliable, safe, and common bedside practices in many ICU environments around the world.

INTRODUCTION

Mass casualty incidents (MCIs) or mass casualty events (MCEs) are characterized by a large number of people becoming injured or ill in a specific event or series of related events. These events can include anthropogenic (human-derived) intentional events (e.g., mass shootings, bombings), anthropogenic nonintentional events (e.g., industrial accidents, structure fires), and natural disasters (hurricanes, earthquakes). Although often unpredictable, such disaster events are increasing such that every medical provider and medical system must be prepared to respond. The most recent example of a long-duration disaster has been the response to the COVID-19 pandemic, in which systems were rapidly overwhelmed in terms of both physical capacity and capability.[1] Since the September 11, 2001, attacks, there has been a particular focus on education and preparation for such events, partly as a result of the increased number of events related to terrorist groups, civilian bombings, and large-scale shootings. This was amplified in 2013 at the Boston Marathon bombing, along with numerous mass shootings at schools and other public venues.[2–4]

One hallmark of most disasters is the presence of major traumatic injuries that require rapid triage, evaluation, and surgical treatment.[5,6] The surgeon plays a critical role in nearly every aspect of disaster management, from preparation and training to the execution and recovery phases. It is critical that surgeons be actively involved in all of the key nonclinical aspects of disaster care, particularly in the local and regional planning and preparatory activities. In many systems, these tasks have been assigned to nonsurgeons and even to nonclinicians, which can result in an unrealistic disaster plan and suboptimal clinical response to the actual event.

Another frequently underappreciated and misunderstood concept in disaster care is the critical role and importance of triage. Among the earliest changes in the way that patients are managed during an MCE is the "sifting and sorting" into categories and their priorities for receiving emergent/urgent care.[7] Although the injury severity and urgency of injured patients will vary somewhat between events, the majority of patients presenting for care will not have major or life-threatening injuries (Fig. 48.1). Further, these minimally injured patients tend to arrive before the more severely injured cohorts, rather than the most severely injured arriving first. This is because less severely injured patients are easier to transport by emergency medical services (EMS) or self-present to the closest emergency department (ED).

Because of the complex nature of disaster responses, high-quality triage may be the most critical physician-driven aspect of initial disaster management. All surgeons should be familiar with the principles and practices of triage in such situations. Appropriate and effective

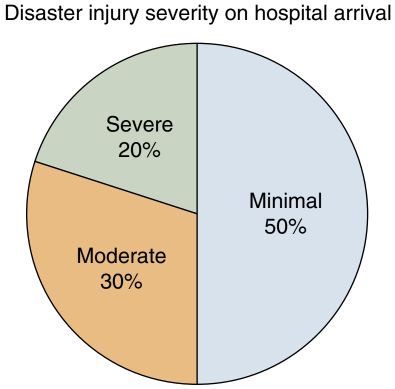

FIGURE 48.1 Most patients who present after a disaster are minimally injured. Approximately 20% of patients are severely injured and should be the focus of immediate interventions.

triage will set the stage for the success or failure of any disaster response by optimizing the match between the injuries and injury severity of the presenting patients and the available critical resources of the facility or system that will be providing care.[8–10]

Ultimately, the goal of any disaster response should be to (1) save the lives of those injured in the event, (2) restore the trauma center or hospital to normal operations as quickly as possible, and (3) learn from the MCI and revise the hospital disaster plan so as to improve future responses. An MCI has a far-reaching impact on a hospital and community, and the lasting effects extend well beyond the hours of the initial response.

HISTORY OF DISASTER

The term *triage* was coined by Napoleon Bonaparte's surgeon, Dr. Baron Larrey. Dr. Larrey poignantly described the importance of addressing the most seriously injured patients first. The military's earliest documented systems of triage date back to the 18th century, and triage is a principal component of disaster care. MCEs are becoming increasingly common, and there are many lessons that can be learned from both the military and civilian systems in terms of triage and trauma systems to optimize care and outcomes for as many casualties as possible.

Triage is a term with its roots in military medicine, and the practice of triage arose from the demands of large amounts of battlefield casualties during war; the original triage concepts were primarily focused on maximal salvage during battlefield injury. Dr. Larrey was known for his surgical leadership and skill and is credited with the development of the concept of "sorting" patients to salvage the greatest number of casualties in a resource-scarce battlefield environment. Dr. Larrey's principals of sorting also included evacuating patients according to the severity of wounding and prioritizing their care based on both the severity of the injury and the likelihood of survival.[11–13]

With each subsequent war since Napoleon's time, military and civilian medical communities have continued to advance the concepts of triage and mass casualty management. As the world becomes increasingly turbulent, with a higher frequency of MCEs, the potential and need for surgeons to be involved in such events are increasing. Surgeon leadership, hospital planning, and community preparation are the first steps to the successful management of these challenging events. Surgeon involvement in every tier of disaster management should be a professional expectation. Although the modern-day surgeon is rarely a prehospital provider, surgeons' comprehensive understanding of the system of trauma care, combined with intricate knowledge of the physiologic effects of injury, gives them unique knowledge for oversight, leadership, and training in relation to MCEs.[4]

MASS CASUALTY INCIDENTS AND MASS CASUALTY EVENTS

The terms *mass casualty incidents* and *mass casualty events* are often used in emergency management and healthcare delivery to describe situations involving a large number of casualties. The term *mass casualty incident* typically refers to an event in which the number of injured or deceased individuals overwhelms the available resources and capabilities of the emergency response system in a specific location. This could include incidents such as natural disasters, industrial accidents, or large-scale transportation accidents. On the other hand, *a mass casualty event* is a broader term that encompasses a wide range of incidents, both intentional and unintentional, resulting in a significant number of casualties. MCEs may include acts of terrorism, pandemics, and other incidents that lead to a substantial impact on public health and safety. Although the terms are sometimes used interchangeably, MCIs are often more localized and immediate, whereas MCIs have a broader scope and may have long-lasting implications on a larger scale.

THE SPECTRUM OF CARE STANDARDS DURING A DISASTER RESPONSE

Disaster response in the hospital setting is a dynamic process that evolves through distinct phases—standard care, contingency care, and crisis care—when confronted with an MCI. Initially, healthcare systems operate under standard care protocols, assuming routine conditions where resources and infrastructure are adequate. However, when faced with an event that overwhelms the system's capacity, a transition to contingency care becomes imperative. During this phase, all healthcare providers adapt and modify practices to optimize the use of available resources without compromising the quality of care. This is an important distinction: During contingency operations, care quality is not significantly affected. Contingency care involves innovative approaches to maintain essential services while responding to the surge in demand.[1]

In the unfortunate event of a catastrophic escalation, hospitals may need to enter the crisis care phase. Here, the emphasis shifts from delivering optimal care to delivering the best possible care under extreme resource constraints. This stage often involves difficult decision-making, such as re-triaging patients based on the severity of their conditions and the likelihood of survival. Ethical considerations become paramount because resources, including medical supplies and personnel, may be insufficient to meet the overwhelming demand.

Effectively navigating these phases requires meticulous planning, coordination, and flexibility. This process will be described in detail later in this chapter. From a surgeon's perspective, preparedness includes not only physical resources like surgical supplies and infrastructure but also training to swiftly adapt to evolving circumstances. A seamless transition between standard care, contingency care, and crisis care is essential to ensure a resilient healthcare response capable of mitigating the impact of MCIs and safeguarding the well-being of those affected.

An important aspect of such a response is appreciating the differences between a surgical team's capability to deal with injury response and a hospital's capacity to manage a large number of patients. In the context of disaster response in hospitals, capacity and capability are distinct but interconnected concepts. *Capacity* refers to the ability of a hospital to accommodate and manage a certain volume of patients, considering factors such as available beds, staff, and resources. It quantifies the physical and logistical limits of the healthcare facility. On the other hand, *capability* refers to the hospital's proficiency in providing specific services and interventions, irrespective of its physical capacity. It encompasses the skills, expertise, and resources necessary to deliver effective medical care. Whereas capacity focuses on the quantity of care a hospital can provide, capability delves into the qualitative aspects of that care, emphasizing the expertise and resources needed for various medical scenarios. During a disaster response, understanding and balancing both capacity and capability are crucial for hospitals to efficiently and effectively manage a surge in patients while maintaining a high standard of care.

During an MCE, the goal of medical personnel is to provide the best possible care to the greatest number of people. In such situations, the standard of care may be compromised because of the sheer volume of patients.[14] Sufficient care is defined as the minimum level of care that is necessary to stabilize a patient's condition and prevent further deterioration. Standard care, on the other hand, is the level of care that would be provided under normal circumstances. During an MCE, medical personnel may have to prioritize patients based on the severity of their injuries and the likelihood of survival. This may mean that some patients receive only sufficient care while others receive standard care.

KEY DEFINITIONS

Under normal circumstances, the term *triage* most frequently applies to the sorting of trauma or critically ill patients in order to direct them to the medical treatment facility with the most appropriate level of capability. Accurate triage results in distributing patients to appropriate hospitals that can expertly manage their condition, whether it is traumatic injury, myocardial infarction, stroke, or sepsis. In terms of trauma, the standard civilian use of the term *trauma triage* refers to the day-to-day function of sending patients to the appropriate hospital/trauma center in order to avoid over- and undertriage. Basic triage optimizes and balances care delivery and resource allocation. Optimizing triage in the face of multiple casualties and potentially limited resources requires leadership, planning, and an established trauma system. Surgeon leadership in the triage process and the trauma system helps establish a well-organized response to disaster. Surgeon involvement in the triage planning and process should occur at every level in a healthcare system: individual, local, regional, and national.

Triage is the process of sorting patients to provide the greatest amount of good for the greatest (highest) number of patients. Success or failure is measured in lives saved or lives lost and resources wasted or appropriately used; success or failure depends on accurate and effective triage.[4]

- Field triage
  Accomplished at or near the scene of the event. The process by which EMS providers decide which hospital to send patients injured by a disaster or traumatic event. Involves collaboration within the field incident command system (ICS).
- Undertriage
  Occurs when seriously injured patients are transported to nontrauma centers or centers that do not have the expertise or capability to manage the severity of the injury.
- Overtriage
  Occurs when patients with minor or nonurgent injuries are transported to major trauma centers or triaged to an immediate care bed. In a disaster situation, this bogs down the system, results in significant bottlenecking, and can result in increased rates of adverse outcomes (Fig. 48.2).

- The goal of field triage is to efficiently concentrate injured patients to major trauma centers without overwhelming these centers with patients who have minor injuries.
- The national benchmarks for field trauma triage are set by the American College of Surgeons Committee on Trauma and are based on system-level rates of undertriage and overtriage.

- Hospital triage
  Sorting patients into predefined categories in order to determine their relative priority of treatment. Patients are separated into groups based on the local triage system that is used. Patients are sorted into categories: those not expected to survive even with treatment; those who will recover with minimal treatment; and the highest-priority group, those who will not survive without treatment.
- Mass casualty incident (MCI)
  Multiple injured patients present simultaneously, but adequate resources are present, and the system is not significantly stressed. An MCI for a large trauma center could be routine, but an MCI may result in a disaster scenario for a small hospital.
- Mass casualty event (MCE)
  Large-scale event that often results in overwhelming numbers of injured or ill patients, as well as frequent destruction or degradation of local infrastructure, which may include the healthcare facilities.

There is a critical distinction between an MCI and MCE that must be understood and appreciated by the treating surgeon.[15]

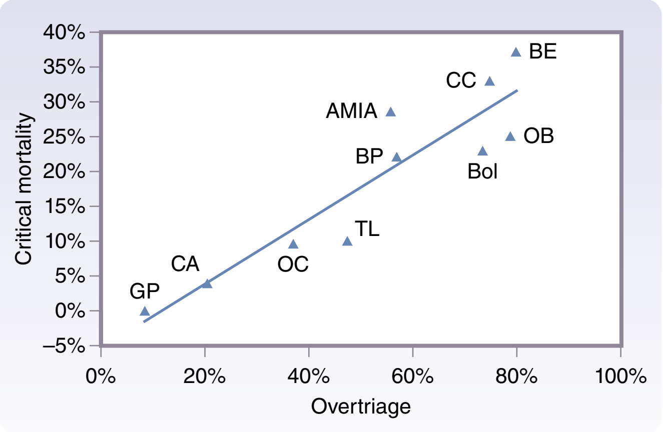

FIGURE 48.2 Relationship between overtriage and critical mortality. One must balance acceptable overtriage with risk of mortality because as it increases, resources are consumed, with resultant increased mortality, as seen in this series of disasters. *AMIA,* Buenos Aires; *BE,* Beirut; *BP,* Birmingham pubs; *Bol,* Bologna; *CA,* Craigavon; *CC,* Cu Chi; *OB,* Old Bailey; *OC,* Oklahoma City; *TL,* Tower of London.

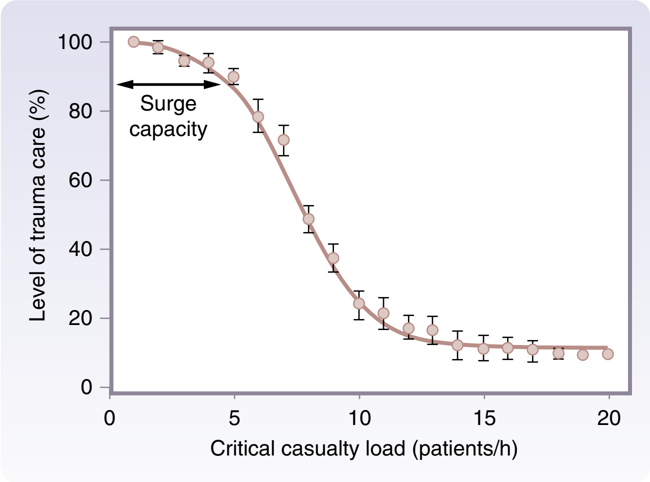

FIGURE 48.3 As patient volume rapidly increases, there is a logarithmic drop in capacity. The goal is to push capacity to the right and thereby increase the total volume of patients a system can manage.

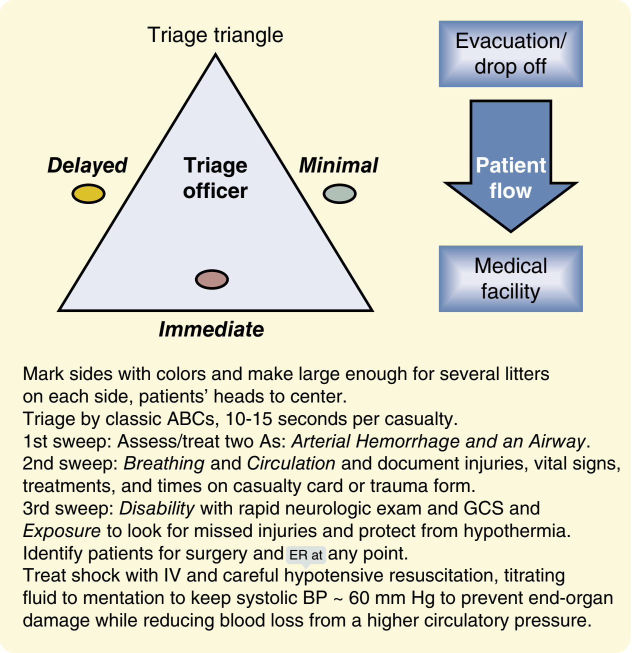
Whereas an MCI requires little to no change in the usual practices and the standard of care, a larger disaster or MCE may result in alternative care pathways with a focus on optimizing group outcomes versus individual patient outcomes. The primary factor that distinguishes these two categories is the relationship between the presenting injuries and the available resources and expertise to care for them. This is commonly referred to as the *surge capacity* for a given facility or system. As shown in Fig. 48.3, the standard level of care can be maintained for a finite number of patients, but once this number is exceeded, there is a precipitous decline in the level of care and associated outcomes. A well-resourced major trauma center may be easily able to handle 20 severely injured patients from one incident, whereas a smaller rural nontrauma center may be overwhelmed with more than 2 or 3 severely injured patients.

HAVE A PLAN

Given the increased requirements placed on a system by an MCE, having a clear plan of action in the event of an MCE is critical to ensure maximal efficiency in the face of unusual circumstances. One of the most critical steps in any disaster response action plan is the delineation of a triage officer. The decision of who is going to be the triage officer should not be made at the time of the disaster event; this should be part of the hospital's established and practiced disaster protocol. For both field and in-hospital triage, the choice of the triage officer should be determined as part of a disaster plan, and the triage officer should be one of the most experienced and organized personnel; for in-hospital triage, the triage officer is frequently an experienced surgeon; and for field triage, either an ED physician or an experienced prehospital provider. It is essential that the triage officer be able to quickly recognize life-threatening injuries. The experience and expertise of the triage officer are crucial; the triage officer must be able to rapidly identify life-threatening injuries and injury patterns and place the patients in the correct triage category. Each hospital and field triage system should have redundancy in the personnel who can serve as the triage officer. Although most triage officers are surgeons, experienced providers in emergency medicine can be excellent triage officers. Disaster plans in the hospital should be rehearsed, and training should be provided. More than one potential triage officer should be identified and train for that role to provide redundancy in the available expertise and also to prepare for scenarios in which the primary triage officer is injured, ill, or otherwise engaged or in which multiple triage points need to be established.

The location for the triage point(s) should be predetermined and clearly spelled out in the written disaster plan and any rehearsal drills. One of the most common errors that we have observed in hospital disaster planning is the development of only one triage plan and location, which fails to appreciate the highly variable nature of these events.[16,17] We recommend the development of at least two flexible triage schemas that allow for the different triage requirements that will be seen in smaller-scale MCIs versus larger-scale or disaster-type events. In general, smaller-scale incidents where all patients can be immediately brought inside the facility require only one primary triage point that is usually optimally located near the ED entrance. Larger-scale MCEs that exceed the available bed space or providers necessitate the establishment of an external primary triage site where patients are categorized, prioritized, and held until they can be moved into the facility (Fig. 48.4).[18,19] Secondary triage would then occur as patients are filtered into the facility and then directed to the appropriate location based on their needed level of care. The external triage location should have climate control, be well lit, and have prestocked supplies for immediate patient needs, including hemorrhage control and airway/breathing interventions. All patients who arrive at the facility must be triaged and ideally enter the hospital through one tightly controlled entry point, with all other facility entrances protected by assigned security personnel.

Field triage protocols benefit trauma systems, but for optimal effect, they must be tailored to local needs and tested in each system for sensitivity and specificity. Training should be provided, and protocols should have a built-in performance improvement mechanism and be monitored by experienced physicians and surgeons who can adjust the protocols when necessary (Figs. 48.5 and 48.6). The American College of Surgeons (ACS) Committee



Mark sides with colors and make large enough for several litters on each side, patients' heads to center.
Triage by classic ABCs, 10-15 seconds per casualty.
1st sweep: Assess/treat two As: *Arterial Hemorrhage and an Airway*.
2nd sweep: *Breathing* and *Circulation* and document injuries, vital signs, treatments, and times on casualty card or trauma form.
3rd sweep: *Disability* with rapid neurologic exam and GCS and *Exposure* to look for missed injuries and protect from hypothermia.
Identify patients for surgery and ER at any point.
Treat shock with IV and careful hypotensive resuscitation, titrating fluid to mentation to keep systolic BP ~ 60 mm Hg to prevent end-organ damage while reducing blood loss from a higher circulatory pressure.

FIGURE 48.5 SALT (Sort, Assess, Lifesaving interventions, Treatment/transport) triage is one example of a triage schema to determine proper patient placement.

Triage and evacuation categories

- Standard NATO nomenclature is recommended, often called "DIME"

🟡 – **Delayed** (yellow tag) – may be life threatening, but intervention may be delayed for several hours with frequent reassessment – (fractures, tourniquet-controlled bleeding, head or maxillofacial injuries, burns)

🔴 – **Immediate** (red tag) – immediate attention required to prevent death; usually "AABC" issue – airway, arterial bleed, ventilation, circulatory

🟢 – **Minimal** (green tag) – ambulatory, minor injuries such as lacerations, minor burns, or musculoskeletal injuries; can wait for definitive attention

⚫ – **Expectant** (black tag) – survival unlikely, such as extensive burns, severe head injuries

FIGURE 48.6 Example matrix of allocation to trauma center levels based on injury severity.

on Trauma (COT) sets national benchmarks for the measurement of field triage accuracy.[20] System-level rates of overtriage and undertriage are established based on objective criteria. Overtriage significantly encumbers the system during MCIs and can result in preventable deaths and system failure. Mathematically, it is defined as 1 − specificity (Fig. 48.7). On the other hand, undertriage could result in transport to nontrauma centers or triage to an inappropriate category at the hospital. This is mathematically defined as 1 − sensitivity (see Fig. 48.7). In usual trauma practice, there is a focus on avoiding undertriage at all costs while accepting the resultant high levels of overtriage. During disasters, this relationship changes to one in which there must be an equal or greater focus on avoiding overtriage as there is on minimizing undertriage in order to optimize outcomes and preserve scarce or critical resources (see Fig. 48.2).

Casualty identification and tracking can be a serious challenge in any disaster.[4] A large number of different triage cards are widely used and can be beneficial if their use is standardized and practiced within a given system. The most common triage cards used are standardized Field Triage Cards.[21,22] As shown in the example in Fig. 48.8, these cards can rapidly display critical information, including vital signs and major injuries, and then easily identify what category or priority has been assigned to that patient. Although these cards have the advantage of simplicity and ease of use, there are downsides and logistic challenges, such as the cards getting lost or not staying with the patient as they move through the system. Writing can also be obscured by blood or be illegible. Like everything else in a disaster response, practice must be provided, and the cards' use must be rehearsed.

The success or failure of a disaster response pivots on many different factors. The best plans may not be able to be implemented secondary to unforeseen events. Disaster planning cannot

		Injury severity	
		Severe (requires Level 1 or 2)	Not severe (requires Level 3 or 4)
Destination decision	Level 1 or 2 TC†	a	b
	Level 3 or 4 TC	c	d

Sensitivity = a/(a + c)
Specificity = d/(b + d)
Rate of undertriage = c/(a + c)
Rate of overtriage = b/(b + d)
Positive predictive value = a/(a + b)
Negative predictive value = d/(c + d)

* In this figure, “a”, “b”, “c”, and “d” represent injured patients, categorized by severity of injury and destination.
† Trauma center.

FIGURE 48.7 North Atlantic Treaty Organization (NATO) triage tags to be placed on a patient.

predict every possible contingency or event. Although leadership, effective triage, and training are all crucial components of success in managing MCIs or MCEs, plans must be able to adapt to unforeseen circumstances. No disaster is the same; however, triage principles and patient management concepts remain the same, but they must be adaptable to the situation.

When plans need to be quickly adapted because of the situation, leadership is crucial. If leaders are unable to adapt, the system will be unable to adapt. Triage, regional and in-hospital response, and overall disaster management are dynamic processes that unfold as the casualty-producing event progresses. Management of triage patients as they move through the system must be performed within the constraints of the scenario and environment and the considerations of the tactical situation.

THREAT ANALYSIS

The triage officer should be informed by the incident commander and prehospital providers to understand the tactical situation in order to appropriately manage resources and meet the goal of doing the best for the most. Awareness of the event, the situation, the estimated number of casualties, the risk for a secondary event, the effectiveness of field triage, and so forth gives the hospital triage officer the proper perspective to facilitate optimization of resources. The triage officer must have good situational awareness and ensure that casualties get treated in a timely and appropriate manner while using resources appropriately to maintain capability for the additional influx of casualties. Coordination and communication are key factors in being able to adapt; there must be redundancy and fail-safes in the communication systems so that as the system adapts to overcome situations not accounted for in disaster planning, all elements of the local and regional teams are kept aware.

HOSPITAL INCIDENT COMMAND SYSTEM

The currently used organizational plan and structure in the United States for sustained responses to large-scale emergency events is the ICS, and at the hospital, this is known as the Hospital Incident Command System (HICS). This provides a generalized and flexible crisis leadership infrastructure that can be implemented across all types of events (the “all-hazards” approach), including disaster events.[23,24] The HICS system broadly consists of an incident commander and four subordinate sections: Operations, Finance, Logistics, and Planning. Additional key personnel serve under each of these sections or provide advisory or liaison functions for the incident commander (Fig. 48.9). A common misperception is that the HICS is the primary entity responsible for disaster response and is the key element at the center of any MCE. It is important to recognize that there is a significant delay between identification of the crisis event with activation of the HICS response and having an operational system in place. In the majority of MCIs, the HICS will not be in place or functional before all of the initial patient transport and urgent care is completed and thus should not be counted on to perform or assist in the early disaster response. For prolonged events, typically natural disasters, the HICS will have a more critical role in supporting key functions, including resupply, coordination of rescue efforts, maintenance and repair of critical equipment or facilities, and coordination with local and federal agencies.[24,25] The critical function of the HICS in each institution was clearly delineated during the early days of COVID, when lockdowns and suspension of noncritical hospital operations were commonplace. Once an MCI/MCE is identified, an HICS program should be immediately implemented.

DRILLS AND TRAINING

Training for disaster events requires surgeon involvement at the local and regional levels. Effective leadership and training are foundational for a successful response to an MCI or MCE; although surgeons are not involved with point-of-injury care and only rarely with field triage, surgeon involvement with planning and training is extremely important. Any trauma system, even the most established, can be burdened by large volumes of patients. Successful triage requires significant training and sorting and prioritizing of casualties according to their injuries while considering the tactical situation and resources available; it is a skill that, in addition to training, requires education and leadership. Additionally, this skill is rarely practiced in clinical settings on this scale and requires frequent reeducation because it is outside of most clinicians’ daily practice.

Although there are many triage categorization schemes, each hospital and trauma system should choose one, keep it simple, and train with it regularly (see Fig. 48.9).[9,17,26] Training requires a significant investment of time, energy, and resources; perfunctory training without stressing the weak areas in the process or involving the entire system will only lead to potential failures should the system be stressed with a disaster event. Surgeon leadership is necessary for disaster training; there is a tendency for triage and disaster training to involve prehospital providers and the initial hospital response, but the training does not get brought into the hospital beyond the ED phase of care. Not involving the operating rooms (ORs) and intensive care units (ICUs) in the disaster training makes the scenarios less realistic and can portend a false sense of success when patients get rapidly moved out of the ED to

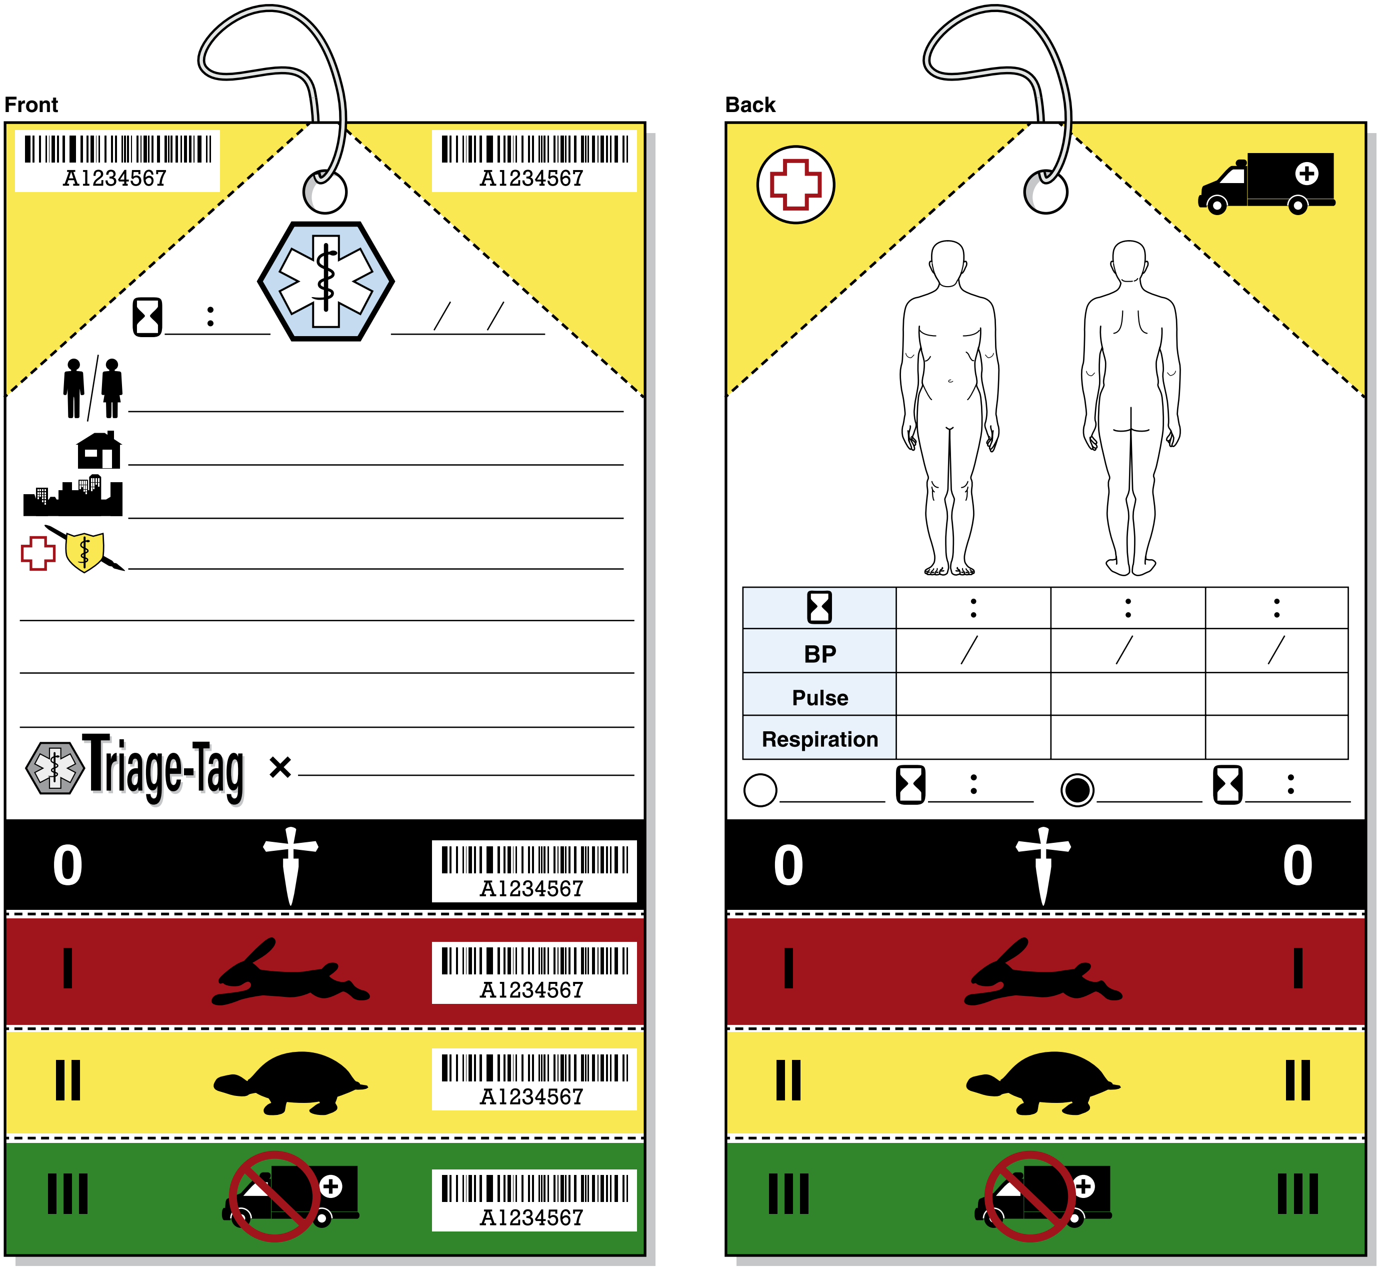

FIGURE 48.8 Example Hospital Incident Command System structure.

go to the ORs without planning for and understanding the time that it takes for multiple operations to occur.[16,27] Although the details and nuances may be second nature to the triage officer, weak areas in the system will be amplified in the event of a disaster scenario. Optimal real-world training is typically resource intensive, and surgeon involvement at all levels will improve the triage and initial response.

Regional readiness for disasters takes coordination, communication, and leadership.[16,18,28,29] The readiness of a hospital and of a community (local and regional readiness) for disaster events is a significant investment that will pay dividends if tragedy strikes. A community being caught off-guard without a rehearsed regional trauma plan will likely pay the price in terms of lives lost. Regional readiness involves coordination with all prehospital elements and first responders. In some communities, there are multiple Level 1 trauma centers, whereas others may have none. Coordination with EMS is essential and can be challenging, given regional EMS organization and communication lines.[30,31] Surgeon involvement at the regional planning levels through regular trauma regional advisory councils will help with coordination and provide a systematic approach.

SURGE COMPONENTS

Although there should be a redundancy of capability, there should not be a redundancy of action; inefficiency must be avoided. As patients are being triaged to different hospitals in the system, both the capability and capacity must be considered, and this should be part of the triage training. *Capability* refers to the current clinical services that would be immediately available at the hospital (neurosurgery, vascular, interventional radiology). *Capacity*, on the other hand, refers to bed status, hospital status, blood available at

the hospital, and OR availability. In a large disaster event, this information is necessary for appropriate field triage. Variations in both capability and capacity status should be rehearsed in regional disaster training. Coordination with hospital and regional incident command centers is necessary for this to occur successfully. Newer web-based tools are now widely available that can greatly aid this process by monitoring and continually updating the status and capabilities of all available hospitals in a given health system or region.[18,32]

SYSTEM INTEGRATION (LOCAL, STATE, FEDERAL)

Multiple systems come into play when considering a prepared community response for a disaster. Both local (in-hospital) and regional (field) triage coordination, planning, training, and process leadership will help minimize loss of life during an MCE, where casualties may be overwhelming. This is why systematic coordination and integration among the multiple hospitals, incident command, prehospital providers, and in-hospital elements are essential. Trauma system coordination occurs through the function of the ACS COT among Level 1 trauma centers; however, as more regional Level 2 trauma centers enter communities, it is imperative that surgeon leadership be involved in the integration of not only the regional triage process but also the incident command centers. These lower-level facilities frequently play a major role in disaster response and can even exceed the role played by the regional Level 1 trauma center. In the Route 91 shooting in Las Vegas that occurred in October 2017, most of the victims were brought to the Level 2 trauma centers around the shooting site.[33] Maintaining good lines of clinician communication and surgeon leadership among the regional trauma centers will continue to integrate and build the system to function well during large casualty events. This requires frequent contact between community sites and a process for delineating patient transport and disbursement from the incident scene that does not overwhelm one trauma center.

From an in-hospital perspective, the function of hospital departments, such as the blood bank, patient transport, radiology, postanesthesia care unit (PACU), ORs, and so forth, relies on integration and coordination within the hospital in order for there to be good patient flow and no bottlenecks. Without reliable integration of the functional areas of the hospital, there is more likely to be increased disorganization, chaos, and delays in patient care. Good system integration does not come without a significant training investment. Surgeon leaders, trauma directors, ED leadership, and nursing leadership must all participate in system integration with the incident command center and the hospital department. These plans cannot just be on paper; they have to be invested in with rehearsals and mock events that stress the system in order to determine the weak areas of system integration. When these weak points and bottlenecks are found, the disaster response plan can be modified and adapted to specific institutional necessities. Events that create large numbers of patients are naturally chaotic and stressful, and a systems integration plan (including backup mechanisms for communication between hospital departments) helps mitigate the chaos inherent to most disasters.

RESPONSE

The surgical management of multiple victims presenting in a mass casualty response should be simultaneously familiar and unfamiliar to a surgeon. The surgical principles and guidelines that govern the care of any traumatically injured patient remain the same. The initial emergent care of any MCI victim should follow standard Advanced Trauma Life Support principles (see Chapter 36). Biologic, chemical, and nuclear terrorism events will require additional specialized response training. Surgeons should consider this training so that they are prepared to provide surgical management for these less common MCEs. The rapidity of patient care during a mass casualty response is commonly heightened, with greater emphasis on damage control surgery and less emphasis on definitive surgical management to allow lifesaving care to be provided to the greatest number of victims in the shortest time possible. The following key lessons from previous MCEs highlight the impact and aftermath of caring for large numbers of victims as well as the importance of promptly returning the hospital to normal function.

HOSPITAL TRIAGE

As discussed previously, triage is an essential tool for ensuring that all patients receive the most appropriate care. Although triage is ideally performed at the scene to identify transport priorities, a recent survey of clinicians responding to worldwide disaster events identified that many victims self-transport, bypassing prehospital triage.[34] These clinicians identified the importance of hospital triage/re-triage as being essential to the success of a disaster response. Triage/re-triage upon arrival to the hospital ensures that all victims receive the necessary care balanced against the available resources.

Various paper and electronic tools have been advocated to facilitate communication and track victims during the triage process. To be effective, these tools must be used routinely on all victims and at all stages of the disaster response continuum. They should also be used during disaster drills so that all providers are familiar with their use in advance of an actual event. Electronic systems that integrate with the hospital's computerized health record may seem attractive, but experience in several large-scale MCEs has found such systems to be lacking.[34] Paper-based systems are easier to use initially but require subsequent manual entry of information into the computerized health record.

The focus during the initial assessment of the mass casualty victim is on immediate lifesaving interventions. Patient history, physical examination, radiographic imaging, and the documentation of these findings are frequently lacking because of the turmoil of the initial response. Previous MCEs have identified that every victim should be thoroughly reexamined and reimaged as appropriate "once the dust has settled" to ensure that no injuries have been missed during the initial response.[34,35]

SURGE CAPACITY

Surge capacity is defined as the ability to increase staff, supplies, equipment, and patient care areas in response to a sudden rise in demand.[34] Advance planning that ensures operative and hospital surge capacity is vital to any mass casualty response. Although each event is different, preparing to accommodate a 20% increase in patient capacity is a reasonable approach during hospital disaster planning. Effective surge capacity is defined by several key principles[35,36]:

- Increase operative capacity:
    - Operative capacity can be rapidly augmented by canceling elective surgical procedures and redeploying available surgical and anesthesia staff. In the Pulse Nightclub mass shooting event in Orlando, 82% of admitted patients required surgery in the first 24 hours, highlighting the importance of operative surge capacity.[36] "Tiered staffing," in which specialized OR or ICU staff are paired with clinical staff from other hospital areas, may also be employed to augment patient care capacity. Another effective strategy involves using an experienced surgeon in the triage area to decide which victims need operative intervention next. This person could be the triage officer or another provider in addition to the triage officer, depending on patient load and operational planning for disaster events. This allows surgeons to remain in the OR rather than moving from triage area to OR and back. Preparing the OR and opening instruments/supplies while the next patient is being transported and anesthesia is induced is also an effective method for reducing turnover time in an MCE. Essential surgical specialties in the first 24 hours after a mass shooting include trauma surgeons, orthopedic and hand surgeons, and vascular surgeons, supported by emergency physicians, intensivists, anesthesia providers, and interventional radiologists.[36] Damage control procedures and multisystem injuries will require frequent trips to the OR in the days after an MCI. Dedicated ORs in the days after an MCE will accommodate those patients who require staged surgery.[36]
- Promptly discharge/downgrade eligible patients:
    - Nonsurgeons, resident physicians, advanced practice providers, and nurses can all function as "discharge teams," increasing hospital bed capacity for incoming victims by downgrading inpatients to lower-acuity beds or discharging appropriate patients to public areas while they await transport out of the hospital.[36]
- Repurpose existing patient care areas:
    - Surge capacity can be achieved by using existing areas of the hospital, such as ambulance bays, procedural areas, PACUs, and even classrooms to perform triage, emergent assessment, and intensive care activities. To be effective, this requires advance planning and practice during disaster drills rather than choosing surge areas in the "heat of the moment." Dedicated disaster supply carts can be created to equip these "surge unit" areas with the resources needed to achieve their intended purpose. These surge units can be created virtually in most computerized health records in advance and activated quickly to facilitate documentation and patient care when the need arises.

- Delegate tasks:
    - Appropriate use of available personnel and delegation of tasks is essential to a successful surge response and a prompt return to normal function. An effective surge response may require clinicians and hospital staff to assume nontraditional duties and perform necessary tasks that are outside of their usual duties.[35] Flexibility in assignments and willingness to perform whatever tasks are needed is an essential component of mass casualty response.[34]

VICTIM TRANSPORTATION

Recent large-scale disasters have demonstrated that many MCI victims present to hospitals via nonconventional means, including private and law enforcement vehicles, bypassing prehospital triage.[34] As such, MCI victims may arrive with little to no warning and with minimal prehospital care. Depending on the nature of the event, a relatively small percentage of victims may present for care via traditional ambulance transport. As those who are most mobile, the initial victims presenting from an MCI may be "walking wounded" patients who require minimal care. Careful triage of the initial wave of victims is essential to ensure that resources remain available for the more critically injured patients to follow.

VICTIM IDENTIFICATION

Disaster victims may be unable to provide information regarding their identity, necessitating the use of alias naming systems until the patient's true identity can be confirmed. In some events, underage victims have been found to have fake identification cards, further contributing to the confusion of the disaster response.[36] In other events, multiple nationalities and/or languages have been involved, requiring the availability of translators and subsequent embassy or consulate support.[35] Sufficient victim aliases should be registered in the hospital's computerized health record well in advance to reduce the burden on the hospital's business office when large numbers of victims present acutely. The advantage of such aliases is that trauma care can be immediately implemented without having to wait for patient registration. Such aliases should remain in use for the first 24 hours of patient care until the chaos of the MCE has abated to avoid the confusion inherent in changing aliases to actual patient names amid active resuscitation and mass transfusion protocols.

COMMUNICATION

Communication (or lack thereof) is a common opportunity for improvement in postdisaster after-action reports.[34] Effective mass casualty communication should consider five "audiences": (1) direct patient care team; (2) local, state, and federal government/law enforcement; (3) hospital staff; (4) victims' families and friends; and (5) community.

- Direct patient care team:
    - Those providing direct patient care need an effective method for communicating patient and resource needs. All mass casualty disaster plans should designate at least a primary and secondary communication system (such as cellular phones and very high-frequency radios). Some cellular phone carriers have systems in place that give priority in a disaster event to first responders and healthcare providers. Registration with such systems must occur in advance of an MCE. In the event of a mass power outage, "runners" may become necessary to disseminate information between HICS and various areas of the hospital. Disaster drills should regularly test the communication tools chosen to ensure that they function properly in all areas of the hospital.
- Local, state, and federal government/law enforcement:
    - Effective communication channels and relationships with key leaders in government and law enforcement should be established well in advance of an MCE. Such relationships are extremely valuable during a disaster response. Disaster drills are an excellent opportunity to develop these relationships by inviting local officials and law enforcement to participate.
- Hospital staff:
    - Every hospital needs an effective system for notifying providers when an MCE has occurred.[34] Such systems should continue to attempt contact with providers until they respond and document when they do. Throughout the event, routine updates should be provided to hospital staff to inform them of the status of the disaster response and important security updates. This can occur via email or a secure hospital website.
- Victims' families and friends:
    - Hospital switchboards are commonly inundated with calls during an MCE by family and friends seeking information regarding loved ones. Messaging for hospital operators should be prepared in advance. A dedicated hotline telephone number to handle victim inquiries should be considered.
- Community:
    - During an MCE, normal hospital operations are frequently limited. The event may also place the local population at risk of injury. Communication with the community regarding the disaster response, alternatives for patient care, and any pertinent public health issues is essential.

BLOOD BANK AND MASSIVE TRANSFUSION

Massive transfusion protocols are now commonplace among trauma and nontrauma hospitals alike. MCEs, however, escalate the burden on hospital blood banks exponentially. Additional blood bank staff will be necessary to prepare the volume of blood products required. The large volume of blood products consumed will also rapidly exhaust even a busy trauma center's blood reserves. A close working relationship and advanced disaster planning with the hospital's blood supplier are essential to ensuring timely availability of blood products. Recent domestic mass shooting events, such as the Pulse Nightclub shooting, have highlighted the ability of the community to respond through blood donation, with over 26,000 units of blood being donated in 72 hours. Although lack of blood products is a common concern, recent MCEs have not identified blood product availability to be a limiting factor in disaster response.[34]

BLOOD-BORNE PATHOGENS

During an MCE, it is common for victims to be exposed to other victims' blood and body fluids.[36] Patients should be offered baseline testing for hepatitis B, hepatitis C, and human immunodeficiency virus (HIV).[37] Patients without previous hepatitis B vaccination should be started on a vaccination program, but postexposure prophylaxis against hepatitis C and HIV is not currently recommended. Because not all victims of disaster events may present to hospitals for medical care, these recommendations should be made known to the community through local television and newspapers.

PRESERVING EVIDENCE

Most MCEs will be considered crime scenes and require investigation by local, state, or federal law enforcement. As such, all victim clothing and belongings should be considered evidence, labeled, preserved with appropriate chain of custody, and held for law enforcement to examine. Appropriate documentation of all injuries sustained, as with any traumatically injured patient, is vital to subsequent investigation. Law enforcement will typically request to interview disaster victims, sometimes before they are reunited with family. Such requests must be balanced against each victim's ongoing care, resuscitation, and need for family notification.

SECURITY

In an MCE, hospital security is paramount. The hospital should be "locked down," with limited, monitored entrances and exits, until all potential threats to the facility have been identified. Hospitals should be considered as possible "secondary targets." Hospital security should plan to be self-sufficient because local law enforcement may be occupied with the disaster response and unable to provide security resources for the hospital.

FINANCE

Disaster response is costly. The finance chief within the HICS structure is tasked with keeping track of all disaster response–associated expenses and labor costs. This should include direct patient care costs and hospital staff compensation (including overtime) as well as the costs of disaster preparation. Government reimbursement for the financial costs incurred may (or may not) be available after the event, but appropriate documentation of expenses will be required.

THE MEDIA

Newspaper, radio, and especially television news crews will arrive soon after any MCI. This can be a distraction to patient care and can violate patient confidentiality if not handled appropriately.[35] Unified hospital messages, distributed through the HICS public information officer, are essential. Regular press conferences with hospital leadership should be scheduled. Surgeons are commonly asked to participate in such press conferences to describe the nature of the disaster, the number of victims, and the medical response required. Media training for surgeon leaders, such as trauma medical directors, should be part of any hospital's disaster planning. Hospital staff should be informed on how to respond to the media's request for comment as well as educated on appropriate social media posts surrounding the disaster response to protect patient confidentiality.[35]

ROLE OF THE HEALTH INSURANCE PORTABILITY AND ACCOUNTABILITY ACT

In a mass casualty situation, the usual rules regarding patient confidentiality, privacy, and disclosure function slightly differently. During Hurricane Katrina in 2005, the Department of Health and Human Services stated, "Health care providers can share patient information as necessary to identify, locate and notify family members, guardians, or anyone else responsible for the individual's care of the individual's location, general condition, or death." This statement allows hospitals and surgeons to disclose limited protected patient health information as needed to identify victims and notify family members of their condition.

FAMILIES AND FRIENDS

In an MCE, the hospital will quickly be inundated with family and friends requesting information about their loved ones. Hospital mass casualty plans must consider not only the family and friends of victims in the hospital but also those of victims who may be deceased at the scene. It frequently falls on hospital physicians and staff to notify families of deceased victims. While awaiting victim identification and notification of outcome, be prepared to provide family and friends with food, water, a place to rest, telephone chargers, translators, and medical care as needed.

COMMUNITY GIVING AND DONATIONS

MCEs commonly result in an outpouring of support from the community. Individuals and businesses will offer to donate their time and services to aid in the response. Donations of food items must be carefully evaluated. A "second-hit" attack on hospital staff through tainted food must always be considered. Donations of material goods also require hospital resources to accept and process them. Monetary donations to legitimate victims' resource funds are an alternative that allows the community to respond while minimizing the impact on hospital personnel and resources. Offers of assistance from healthcare providers outside the credentialed hospital staff must be carefully considered and should follow routine medical staff processes. Disaster responses tend to attract individuals claiming to be healthcare providers when, in fact, they are not.

VISITS FROM VERY IMPORTANT PERSONS

After a disaster response, it is common for elected officials to visit the trauma center/hospital and participate in press conferences.[35] Such visits can be helpful in gaining governmental support for the response efforts. These visits can also place a burden on the hospital, however, because the security required and diversion of hospital staff from patient care responsibilities. Well-intentioned visits from politicians, celebrities, and other prominent individuals immediately after the event can detract from patient care and require hospital resources that are best focused initially on the victims and their families. Such visits are more appropriately arranged for a later time when they can help encourage patients and staff.

STAFF COUNSELING

The impact of an MCE on hospital staff cannot be underestimated. A plan for staff counseling should be part of any hospital disaster plan.[35] Counselors should be made immediately available so that staff who wish to participate in critical incident stress debriefing may have that opportunity before they leave the hospital. Staff schedules should be adjusted to allow those who responded sufficient time to decompress before their next shift. It is important to recognize that individuals cope with the stress of an MCE in different ways. Some team members will wish to speak with a trained counselor, whereas others will simply want to spend time with individuals from their unit or department. Some will seek counseling immediately, whereas others may recognize the need for counseling days to weeks later. Some staff will require counseling for weeks to months after an MCE. Havron et al. studied surgical residents who responded to the 2016 Pulse Nightclub shooting; 30% met the criteria for posttraumatic stress disorder, and 30% met the criteria for major depression, as assessed at 3 and 7 months after the incident.[38]

RETURNING TO NORMAL OPERATIONS

During an MCE, normal clinical operations, including nonemergent surgery and usual trauma patient arrivals, are commonly placed on hold to focus on the victims of the event. The care of preexisting inpatients, as well as critical hospital services such as trauma care, stroke alerts, and myocardial infarction care, must continue, however. The hospital surge plan must include strategies for caring for both disaster victims and current inpatients. The goal of any hospital disaster plan must include the actions required to restore the trauma center/hospital to normal clinical operations as quickly as possible.

ROLE OF REGIONAL MEDICAL OPERATIONS CENTERS IN TRAUMA RESPONSE TO DISASTER

Role of Regional Medical Operations Coordination Centers in Trauma Response to Disaster (RMOCCs) can serve as a critical component in disaster response, providing a centralized hub for coordination, communication, and resource management across various healthcare entities within a specific geographic region. RMOCCs are relatively uncommon in most of the United States, with a few notable exceptions.[39] They serve to enhance the overall efficiency and effectiveness of the healthcare response during crises. The RMOCC acts as a bridge between individual hospitals, public health agencies, EMS, and other healthcare organizations, fostering collaboration and ensuring a unified approach to managing resources and responding to incidents. The overarching goal is to get the right patient to the right place at the right time.[40,41]

Use of an RMOCC involves real-time information exchange, resource allocation, and strategic decision-making. It facilitates the coordination of medical assets, personnel, and supplies to address the evolving needs of a disaster or public health emergency. The RMOCC enables a more cohesive and synchronized response, helping hospitals optimize their capacity and capability during challenging circumstances.

For example, during a large-scale natural disaster, such as a hurricane or a widespread infectious disease outbreak, an RMOCC would play a pivotal role. It could coordinate the distribution of medical supplies, manage patient transportation, and provide a centralized communication platform for healthcare providers to share critical information. By consolidating information and resources, the RMOCC ensures that healthcare facilities are adequately supported, reducing duplication of efforts and enhancing the collective ability to respond effectively to the demands of the emergency. The RMOCC concept exemplifies the importance of regional collaboration in safeguarding public health during crises.

A NATIONAL MODEL FOR DISASTER PREPAREDNESS

A national injury disaster plan does not currently exist in the United States.[42] A future national trauma and emergency preparedness system (NTEPS) would be the next level of coordination beyond RMOCCs to a larger geographic care coordination system.[43,44] Conceptually, a national system would ensure access to high-quality, lifesaving trauma care for anyone, regardless of their location.[1]

An NTEPS would support public health readiness and coordination of care during MCIs, ultimately saving more lives during larger MCEs. Such an established system would facilitate equitable access to high-quality emergency care across the United States.[39] Lessons learned in several states during the COVID-19 pandemic support such a novel approach. The strengths of highly functional state/regional care systems and RMOCCs would facilitate the work of individual surgeons who would be end users of such a care system.

POSTEVENT PROCESSING AND IMPROVEMENT

Among the most important and frequently overlooked aspects of improving disaster care at every level is the need to capture, process, and then act on the feedback and lessons learned from past events. This is critical for both actual disasters and training exercises. Although success or failure during an MCI or MCE may be based on accurate and effective triage, the success or failure of the next event depends on a structured after-action report (AAR) of each event in order to improve individuals, groups, and systems. Although there are many different formats and techniques for performing an effective AAR, they all have several characteristics in common that should be highlighted.

The AAR should be completed as soon after the event as possible to capture events while they are fresh in people's minds and ensure maximal participation. AARs should be completed at every level, from an individual department or area (ED, OR, ICU) up to the facility level and even the system level. The AAR should focus on gathering input in two categories: things that went well or worked and things that did not work or need to be improved. In particular, any obvious areas that resulted in suboptimal outcomes, patient/provider harm, or near misses should be identified. This should be done in an entirely nonjudgmental and nonpunitive manner, and input from all levels should be encouraged. A formal report of the AAR should be created and submitted up the chain of command to be integrated into the hospital- or system-level AAR. Finally, and most importantly, an action plan based on the AAR feedback and review should be created that identifies and prioritizes changes to be implemented to better prepare for future disaster events. Institutionalization of processes like this, with the aim of continual improvement of the delivery of care and focused on the patient at the center, characterize the "Learning Health System." This concept was emphasized and codified in a recent National Academies of Science, Engineering, and Medicine report, "Zero Preventable Deaths," calling for an overhaul of the national trauma systems in the United States.[29,45]

Several large-scale events in the relatively recent past are illustrative of postevent processing improvements throughout health systems, both those that responded to the events and those preparing for such disasters in other communities. One of the most cited successful examples was that of the citywide response to the Boston Marathon bombing in 2013. The scene triage and distribution of patients during this disaster allowed for rapid transport and care for a large population of critically injured patients.[3,46] Although this is a great example of how to distribute patients to trauma centers, the area of the attack was uniquely situated almost equidistant to five Level 1 trauma centers, allowing for access to the highest level of care in a time frame that is difficult to replicate in almost any other area of the country. Another aspect that was thoroughly studied during this attack was scene safety because the detonation of the second bomb raised concerns about the possibility of further attacks, specifically targeting first responders.

The Pulse Nightclub shooting in Orlando and the Route 91 shooting in Las Vegas both provided unique lessons relating to large-scale ballistic MCEs. Both of these demonstrated that large numbers of patients can appear at trauma centers via nonconventional means (civilian transport, police transport, etc.), which can make accurate assessment and on-scene triage exceedingly difficult. This emphasizes the need for accurate on-scene data and communication between centers regarding surge capacity because accurate patient flow from the scene to patient centers may be difficult to impossible to assess in real time at the scene of the incident. The Pulse Nightclub mass shooting clearly highlights the need for understanding of a center's true surge capacity; in this incident, 82% of patients required urgent surgery within the first 24 hours of arrival at the trauma center, placing a strain on resources.[36] In the Las Vegas shooting in 2017, most of the victims were brought to Level 2 centers around the site of the shooting. This highlights the need for involvement of Level 2 centers in regional training for MCIs and the critical nature of communication between all centers, regardless of designation level.[33]

In July of 2013, an Asiana Airline crash occurred in San Francisco, sending 187 patients to hospitals in the Bay Area. Most of these patients were non–English speaking, placing an unusual strain on the hospital systems based on both provider resources and translation ability. Given that San Francisco is a hub for travel to Asia from the United States, this is a somewhat unique aspect of mass casualty response for that city and provides a great example of how postevent processing can allow for improvement in a previously unthought-of area of mass casualty response.

In all of these specific examples, postevent processing allowed for identification of what portions of the systems performed admirably and what portions required improvement. Documentation and dissemination of this information within the involved systems allow for improvement in mass casualty response for possible future encounters, and publication of some of this information has allowed other health systems to refine their processes based on shared information.

CHAPTER 49

Transplantation Immunobiology and Immunosuppression

William H. Kitchens, Idelberto Raul Badell, and Andrew B. Adams

OUTLINE

The Immune Response
  - Innate Immunity
  - Monocytes
  - Dendritic Cells
  - Natural Killer Cells
  - Acquired Immunity
  - Major Histocompatibility Locus: Transplant Antigens
  - Human Histocompatibility Complex

Transplant Immunity
  - Rejection
  - Hyperacute Rejection
  - Acute Rejection
  - Chronic Rejection

Immunosuppression
  - Induction Therapy
  - Maintenance Immunosuppression

Novel Therapies Targeting B Cells and Antibodies
  - Complications of Immunosuppression

Tolerance
  - Lymphocyte Depletion
  - Costimulation Blockade
  - Chimerism
  - Adoptive Cell Transfer Therapy

New Areas of Transplantation
  - Xenotransplantation
  - Machine Perfusion
  - Bioartificial Organs

Conclusion

Only a few short decades ago, there were no options for patients dying of end-stage organ failure. The concept of transplanting an organ from one individual to another was thought to be impossible. The evolution of clinical transplantation and transplant immunology is one of the bright success stories of modern medicine. It was through understanding of the immune response to the transplanted tissue that pioneers in the field were able to develop therapies to manipulate the immune response and to prevent rejection of the transplanted organ. Today, more than 25,000 transplants are performed annually, and over 100,000 patients are currently listed and awaiting an organ.

The concept of transplantation is certainly not new. History is replete with legends and myths recounting the replacement of limbs and organs. An oft-repeated myth of early transplantation is derived from the miracle of Saints Cosmas and Damian (brothers and subsequently patron saints of physicians and surgeons) in which they successfully replaced the gangrenous leg of the Roman deacon Justinian with a leg from a recently deceased Ethiopian (Fig. 49.1). It was not, however, until the French surgeon Alexis Carrel developed a method for joining blood vessels in the late 19th century that the transplantation of organs became technically feasible and verifiable accounts of transplantation began (Fig. 49.2). He was awarded the Nobel Prize in Medicine in 1912 "in recognition of his work on vascular suture and the transplantation of blood vessels and organs." Having established the technical component, Carrel himself noted that there were two issues to be resolved regarding "the transplantation of tissues and organs . . . the surgical and the biological." He had solved one aspect, the surgical, but he also understood that "it will only be through a more fundamental study of the biological relationships existing between living tissues" that the more difficult problem of the biology would come to be solved.

Forty years would pass before another set of eventual Nobel Prize winners, Peter Medawar and Frank Macfarlane Burnet, would begin to define the process by which one individual rejects another's tissue (Fig. 49.3).[1] Medawar and Burnet had developed an overall theory on the immunologic nature of self and the concept of immunologic tolerance. Burnet hypothesized that the definition of "self" was not preprogrammed, but rather actively defined during embryonic development through the interaction of the host's immune cells with its own tissue. This hypothesis implied that tolerance could be induced if donor cells were introduced to the embryo within this developmental period. Burnet was proven correct when Medawar showed that mouse embryos receiving cells from a different mouse strain accepted grafts from the strain later in life while rejecting grafts from other strains. These seminal studies were the first reports to demonstrate that it was possible to manipulate the immune system to accept allografts.[1]

Shortly thereafter, Joseph Murray, Nobel Laureate 1990, performed the first successful renal transplant between identical twins in 1954.[2] At the same time, Gertrude Elion, who worked as an assistant to George Hitchings at Wellcome Research Laboratories, developed several new immunosuppressive compounds, including 6-mercaptopurine and azathioprine. Roy Calne, a budding surgeon-scientist who came from the United Kingdom to study with Murray, subsequently tested these reagents in animals and then introduced them into clinical practice, permitting nonidentical transplantation to be successful. Elion and Hitchings later shared the Nobel Prize in 1988 for their work on "the important principles of drug development." Subsequent discovery of increasingly effective agents to suppress the rejection response has led to the success in allograft survival that we enjoy today. It is this collaboration between scientists and surgeons that has driven our understanding of the immune system as it relates to transplantation. In this chapter, we provide an overview of the immune response with specific attention to transplant immunity and the rejection process, review the specific immunosuppressive agents that are employed to prevent rejection, and provide a glimpse into the future of the field.

THE IMMUNE RESPONSE

The immune system, of course, did not evolve to prevent the transplantation of another individual's tissue or organs; rejection, rather, is a consequence of a system that has developed over thousands of years to protect against invasion by pathogens and to prevent subsequent disease. To understand the rejection process and in particular to appreciate the consequences of pharmacologic suppression of rejection, a general understanding of the immune response as it functions in a physiologic setting is required.

The immune system has evolved to include two complementary divisions to respond to disease: the innate and acquired immune systems. Broadly speaking, the innate immune system recognizes general characteristics that have, through selective pressure, come to represent universal pathologic challenges to our species (ischemia, necrosis, trauma, and certain conserved nonhuman molecules such as unmethylated CpG oligodeoxynucleotide DNA). The acquired arm, on the other hand, recognizes specific structural aspects of foreign substances, usually peptide or carbohydrate moieties, recognized by receptors generated randomly and selected to avoid self-recognition. Although the two systems differ in their specific responsibilities, they act in concert to influence each other to achieve an optimal overall response.

Innate Immunity

The innate immune system is thought to be a holdover from an evolutionarily distant response to foreign pathogens. In contrast to the acquired immune system, which employs an innumerable host of specificities to identify any possible antigen, the innate system uses a select number of protein receptors to identify specific motifs consistent with foreign or altered and damaged tissues. These receptors can exist on cells, such as macrophages, neutrophils, and natural killer (NK) cells, or free in the circulation, as is the case for complement. Whereas they fail to exhibit the specificity of the T-cell receptor (TCR) or antibody, they are broadly reactive against common components of pathogenic organisms, for example, lipopolysaccharides on gram-negative organisms or other glycoconjugates. Thus, the receptors of innate immunity are the same from one individual to another within a species and, in general, do not play a role in the direct recognition of a transplanted organ. They do, however, exert their effects indirectly through the identification of "injured tissue" (e.g., as is the case when an ischemic, damaged organ is moved from one individual to another).

Once activated, the innate system performs two vital functions. It initiates cytolytic pathways for the destruction of the offending organism, primarily through the complement cascade and NK cells. In addition, the innate system can shape the development of a concomitant acquired immune system response both through production of an immunomodulatory cytokine milieu and through enabling the activation and maturation of antigen-presenting cells (APCs). Macrophages and dendritic cells not only engulf foreign organisms that have been bound by complement but also distinguish pathogens, as they can be identified through receptors for foreign carbohydrates (e.g., mannose receptors). A highly evolutionarily conserved family of proteins known as *toll-like receptors (TLRs)* has been described to play an important role as activation molecules for innate APCs. They bind to pathogen-associated molecular patterns, motifs common to pathogenic organisms. Some examples of TLR ligands include lipopolysaccharide, flagellin (from bacterial flagella), double-stranded viral RNA, unmethylated CpG islands of bacterial and viral DNA, zymosan (β-glucan found in fungi), and numerous heat shock proteins. In contrast to pathogen-associated molecular patterns, which initiate a response to an infectious challenge, damage-associated molecular pattern molecules (DAMPs), also called *alarmins,* trigger the innate inflammatory response to noninfectious cell death and injury. Many DAMPs are nuclear or cytosolic proteins or even DNA that is released or exposed in the setting of cell injury. These signals alert the innate immune system that injury has occurred and a response is required. DAMP receptors include some of the TLRs, including TLR2 and TLR4, but also a variety of other proteins, such as receptor for advanced glycosylation end-products (RAGE) and triggering receptor expressed on myeloid cells 1 (TREM-1). In the setting of a transplant surgery where an organ is cut out of one individual with a period of obligatory ischemia, cooled to near freezing, and then replaced in another individual, DAMPs play an active role in stimulating the innate inflammatory response. Once an injury or infectious insult has been identified, the cellular components of the innate system begin to initiate a response.

Monocytes

Mononuclear phagocytes are bone marrow–derived cells that initially emerge as monocytes within peripheral blood. In the setting of certain inflammatory signals, they home to sites of injury or inflammation, where they mature and become macrophages. Their function is to acquire, process, and present antigen as well as to serve as effector cells in certain situations. Once activated, they elaborate various cytokines that regulate the local immune response. They play a significant role in facilitating the acquired T-cell response through antigen presentation, and their cytokines induce substantial tissue dysfunction in sites of inflammation. Thus, their recruitment to sites of injury and cell death can subsequently provoke T-cell activation and rejection.

Dendritic Cells

Dendritic cells are some of the most potent APCs, and they are distributed throughout the lymphoid and nonlymphoid tissues of the body. Immature dendritic cells can be found along the gut mucosa, within the skin, and in other sites of antigen entry. Once they have encountered antigen in sites of injury, they undergo a process of maturation, including the upregulation of both major histocompatibility complex (MHC) molecules, class I and class II, as well as various costimulatory molecules. They also begin to migrate toward peripheral lymphoid tissue (i.e., lymph nodes), where they can interact with antigen-specific T cells and potentiate their activation. The dendritic cell is involved in the licensing of CD8+ T cells for cytotoxic function, stimulates T-cell clonal expansion, and provides signals for helper T cell (Th) differentiation. There are also subsets of dendritic cells that serve distinct functions in inducing and regulating the cellular response. For example, myeloid dendritic cells are more immunogenic, whereas plasmacytoid dendritic cells are more tolerogenic and may work to suppress the immune response. Follicular dendritic cells are another subset of dendritic cells largely restricted to lymph nodes, and they play a critical role in shaping B-cell responses to antigens and in promoting the development of long-lived memory B-cell and antibody-secreting cell responses.

Natural Killer Cells

NK cells are large granular lymphocytes with potent cytolytic function that constitute a critical component of innate immunity. They were initially discovered during studies focused on tumor immunology. A small subset of lymphocytes exhibited the ability to lyse tumor cells in the absence of prior sensitization, described as "naturally" reactive. These "natural killer" cells exhibited rapid cytolytic activity and existed in a relatively mature state (i.e., morphology characteristic of activated cytotoxic lymphocytes—large size, high protein synthesis activity with abundant endoplasmic reticulum, and rapid killing activity). Further studies have indicated that NK cells lyse cell targets that lack expression of self class I MHC, termed the *missing self hypothesis,* a situation that could arise as a result of viral infection with suppression of self class I molecules or in tumors under strong selection pressure of killer T cells. Since those initial studies, NK cells have been found to express cell surface inhibitory receptors, which include killer inhibitory receptors. These molecules function to deliver inhibitory signals when they bind self class I MHC molecules, thus preventing NK-mediated cytolysis on otherwise healthy host cells. NK cells produce various cytokines, including interferon-γ (IFN-γ), which may function to activate macrophages, which can in turn eliminate host cells infected by intracellular microbes. Similar to macrophages, NK cells express cell surface Fc receptors, which bind antibody and participate in antibody-dependent cellular cytotoxicity. NK cells also play an important role in the immune response after bone marrow transplantation and xenotransplantation. Their role in solid organ transplantation is less well defined, although there is some evidence that they may participate in acute and chronic allograft rejection.

Acquired Immunity

The distinguishing feature of the acquired immune system is specific recognition and disposition of foreign elements as well as the ability to recall prior challenges and to respond appropriately. Highly specific receptors, discussed later, have evolved to distinguish foreign from normal tissue through antigen binding. The term *antigen* is used to describe a molecule that can be recognized by the acquired immune system. An epitope is the portion of the antigen, generally a carbohydrate or peptide moiety, that actually serves as the binding site for the immune system receptor and is the base unit of antigen recognition. Thus, there may be one or many epitopes on any given antigen. The acquired response is divided into two distinct arms: cellular and humoral. The predominant effector cell in each arm is the T cell and B cell, respectively. Accordingly, the two main types of receptors that the immune system employs to recognize any given epitope are the TCR and B-cell receptor (BCR, or antibody). In general, individual T or B lymphocytes express identical receptors, each of which binds only to a single epitope. This mechanism establishes the specificity of the acquired immune response. The antigenic encounter alters the immune system such that future challenges with the same antigen provoke a more rapid and vigorous response, a phenomenon known as *immunologic memory.* There are vast differences in the way each division of the acquired immune response identifies an antigen. The BCR or antibody can identify its epitope directly without preparation of the antigen, either on an invading pathogen itself or as a free-floating molecule in the extracellular fluid. T cells, however, recognize only their specific epitope after it has been processed and bound to a set of proteins unique to the individual, which are responsible for presentation of the antigen. This set of proteins, crucial to antigen presentation, are termed *histocompatibility proteins* and, as their name suggests, were defined through studies examining tissue transplantation. The case of the immune response in tissue transplantation is unique and is discussed in its own section.

Major Histocompatibility Locus: Transplant Antigens

The MHC refers to a cluster of highly conserved polymorphic genes on the sixth human chromosome. Much of what we know about the details of the immune response grew from initial studies defining the immunogenetics of the MHC. Studies began in mice in which the MHC gene complex, termed *H-2,* was described by Gorer and Snell as a genetic locus that segregated with transplanted tumor survival. Subsequent serologic studies identified a similar genetic locus in humans called the *human leukocyte antigen (HLA) locus.* The products of these genes are expressed on a wide variety of cell types and play a pivotal role in the immune response. They are also the antigens primarily responsible for human transplant rejection, and their clinical implications are discussed later.

MHC molecules play a role in both the innate and acquired immune systems. Their predominant role, however, lies in antigen presentation within the acquired response. As mentioned earlier, the TCR does not recognize its specific antigen directly; rather, it binds to the processed antigen that is bound to cell surface proteins. It is the MHC molecule that binds the peptide antigen and interacts with the TCR, a process called *antigen presentation.* Thus, all T cells are restricted to an MHC for their response. There are two classes of MHC molecules: class I and class II. In general, CD8+ T cells bind to antigen within class I MHC, and CD4+ T cells bind to antigen within class II MHC.

Human Histocompatibility Complex

The antigens primarily responsible for human allograft rejection are those encoded by the HLA region of chromosome 6 (Fig. 49.4). The polymorphic proteins encoded by this locus include class I molecules (HLA-A, B, and C) and class II molecules (HLA-DP, DQ, and DR). There are additional class I genes with limited polymorphism (E, F, G, H, and J), but they are not currently used in tissue typing for transplantation and are not considered here. There are class III genes as well, but they are not cell surface proteins involved in antigen presentation directly, but instead include molecules that are pertinent to the immune response by various mechanisms: tumor necrosis factor-α (TNF-α), lymphotoxin β, components of the complement cascade, nuclear transcription factor-β, and heat shock protein 70. Other conserved genes within the HLA include genes necessary for class I and class II presentation of peptides, such as the peptide transporter proteins TAP1 and TAP2 and proteasome proteases LMP2 and LMP7.[3] Although other polymorphic genes, referred to as *minor histocompatibility antigens,* exist in the genome outside of the HLA locus, they play a less significant role in transplant rejection and are not covered here. It is, however, important to point out that even HLA-identical individuals are subject to rejection on the basis of these minor differences. The blood group antigens of the ABO system must also be considered transplant antigens, and their biology is critical to humoral rejection.

Although initially identified as transplant antigens, class I and class II MHC molecules actually play vital roles in all immune responses, not just those to transplanted tissue. HLA class I molecules are present on all nucleated cells. In contrast, class II molecules are found almost exclusively on cells associated with the immune system (macrophages, dendritic cells, B cells, and activated T cells) but can be upregulated and appear on other parenchymal cells in the setting of cytokine release caused by immune response or injury.

The importance to transplantation of MHC gene products stems from their polymorphism. Unlike most genes, which are identical within a given species, polymorphic gene products differ in detail while still conforming to the same basic structure. Thus, polymorphic MHC proteins from one individual are foreign

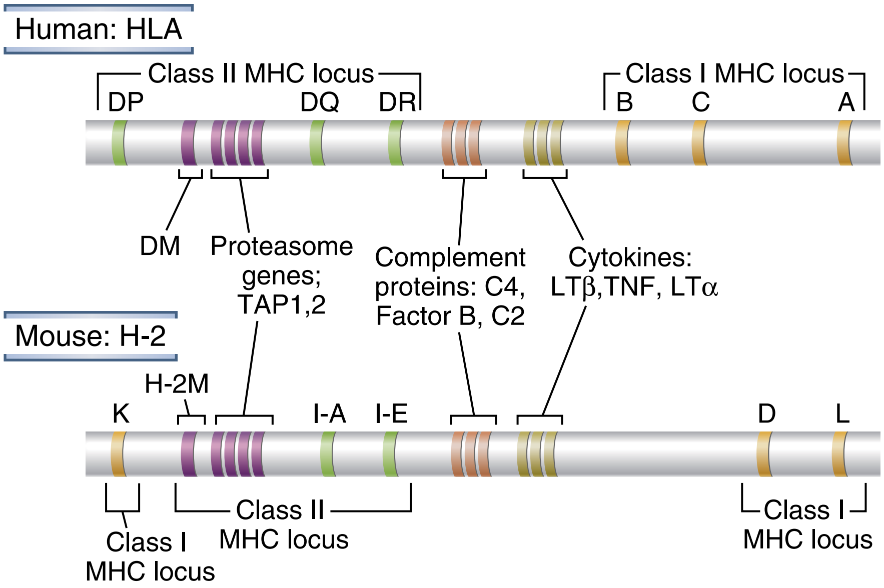

FIGURE 49.4 Schematic maps of human and mouse major histocompatibility complex *(MHC)* loci. The basic organization of the genes in the MHC locus is similar in humans and mice. *HLA,* Human leukocyte antigen; *LT,* lymphotoxin; *TAP,* transporter associated with antigen processing; *TNF-α,* tumor necrosis factor-α. (Adapted from Abbas AK, Lichtman AH, Pillai S. *Cellular and Molecular Immunology*. 10th ed. Philadelphia: Saunders Elsevier; 2021.)

alloantigens to another individual. Recombination within the HLA locus is uncommon, occurring in approximately 1% of molecules. Consequently, the HLA type of the offspring is predictable. The unit of inheritance is the haplotype, which consists of one chromosome 6 and, therefore, one copy of each class I and class II locus (HLA-A, B, C, DP, DQ, and DR). Thus, donor-recipient pairings that are matched at these HLA loci are referred to as *HLA-identical allografts,* and those matched at half of the HLA loci are termed *haploidentical*. Note that HLA-identical allografts still differ genetically at other genetic loci and are distinct from isografts. Isografts are organs transplanted between identical twins and are immunologically indistinguishable and thus are not naturally rejected. The genetics of HLA is particularly important in understanding clinical living related donor transplantation. Each child inherits one haplotype from each parent; therefore, the chance of siblings being HLA identical is 25%. Haploidentical siblings occur 50% of the time, and completely nonidentical or HLA-distinct siblings occur 25% of the time. Biologic parents are haploidentical with their children unless there has been a rare recombination event. The degree of HLA match can also improve if the parents are homozygous for a given allele, thus giving the same allele to all children. Likewise, if the parents share the same allele, the likelihood of that allele being inherited improves to 50%. This is even more important in the field of bone marrow transplantation in which the risks of donor-mediated cytotoxicity and resultant graft-versus-host disease become a more relevant issue.

Each class I molecule is encoded by a single polymorphic gene that is combined with the nonpolymorphic protein β_2 microglobulin (chromosome 15) for expression. The polymorphism of each class I molecule is extreme, with 40 to 130 alleles per locus. Class II molecules are made up of two chains, α and β, and individuals differ not only in the alleles represented at each locus but also in the number of loci present in the HLA class II region. The polymorphism of class II is thus increased by combinations of α and β chains as well as by hybrid assembly of chains from one class II locus to another. As the HLA sequence varies, the ability of various peptides to bind to the molecule and to be presented for T-cell recognition changes. Teleologically, this extreme diversity is thought to improve the likelihood that a given pathogenic peptide will fit into the binding site of these antigen-presenting molecules, thus preventing a single viral agent from evading detection by T cells of an entire population.[4]

Class I Major Histocompatibility Complex

The three-dimensional (3D) structure of class I molecules (HLA-A, B, and C) was first elucidated in 1987.[5] The critical structural feature of class I molecules is the presence of a groove formed by two α helices mounted on a β pleated sheet (Fig. 49.5). Within this groove, a 9–amino acid peptide, formed from fragments of proteins being synthesized in the cell's endoplasmic reticulum, is mounted for presentation to T cells (Fig. 49.6). Almost all the significant sequence polymorphism of class I is located in the region of the peptide-binding groove and in areas of direct T-cell contact. In general, all peptides made by a cell are candidates for presentation, although sequence alterations in this region favor certain sequences over others.

Human class I presentation occurs on all nucleated cells, and expression can be increased by certain cytokines, thus allowing the immune system to inspect and to approve of ongoing protein synthesis. IFNs (IFN-α, IFN-β, and IFN-γ) induce an increase in the expression of class I molecules on a given cell by increasing levels of gene expression. T-cell activation occurs when a given T cell encounters a class I MHC molecule carrying a peptide from a nonself protein presented in the proper context (e.g., viral protein is processed in an infected cell and the peptide fragments are presented on class I molecules for T-cell recognition). So-called *cross-presentation* may also occur in which certain APCs, namely, a subset of dendritic cells, have the ability to take up and process exogenous antigen and present it on class I molecules to CD8+ T cells.[6] In the case of transplantation, this activation is not only possible when foreign peptide is identified after the donor MHC

has been processed and presented on recipient APCs but is thought to more commonly occur when a T cell interacts directly with the donor nonself class I MHC, the so-called *direct alloresponse*.

Class II Major Histocompatibility Complex

The class II molecules are products of the *HLA-DP, HLA-DQ*, and *HLA-DR* genes. The structural features of class II molecules are strikingly similar to those of class I molecules. The 3D structure of class II molecules was inferred by sequence homology to class I in 1988 and eventually proven by x-ray crystallography in 1993 (Fig. 49.7).[7] The class II molecules contain two polymorphic chains, one approximately 32 kDa and the other approximately 30 kDa. The peptide-binding region is composed of the α1 and β1 domains. As with the class I molecule, significant polymorphic residues of class II are located in the peptide-binding clefts and in the alpha helices around these clefts. Class II molecule assembly requires association of both the α chain and β chain in combination with a temporary protein called the *invariant chain*.[8] This third protein covers the peptide-binding groove until the class II molecule is out of the endoplasmic reticulum and is sequestered in an endosome. Proteins that are engulfed by a phagocytic cell are degraded at the same time as the invariant chain is removed, allowing peptides of external sources 11 to 30 amino acids long to be associated with and presented by class II (see Fig. 49.6). In this way, the acquired immune system can inspect and approve of proteins that are present in circulation or that have been liberated from foreign cells or pathogens through

the phagocytic process. Accordingly, class II molecules, in contrast to class I molecules, are confined to cells related to the immune response, particularly APCs (macrophages, dendritic cells, B cells, and monocytes). Class II expression can also be induced on other cells, including endothelial cells, under the appropriate conditions. After binding class II molecules, CD4+ T cells participate in APC-mediated activation of CD8+ T cells and antibody-producing B cells. In the case of transplanted organs, ischemic injury at the time of transplantation accentuates the potential for T-cell activation by upregulation of both class I and class II molecules locally on the recipient. The trauma of surgery and ischemia also upregulates class II on all cells of the allograft, making nonself MHC more abundant. Host CD4+ T cells may then recognize donor MHC directly (direct alloresponse) or after antigen processing on the recipient's own MHC (indirect alloresponse) and then proceed to participate in rejection.

Human Leukocyte Antigen Typing: Implications for Transplantation

For the reasons already discussed, closely matched or less mismatched transplants are less likely to be recognized and rejected than are similar grafts differing by multiple alleles at the MHC. The degree of HLA matching has historically had clear influence on the prolongation of graft survival. Humans potentially have two different HLA-A, B, and DR alleles (one from each parent, six in total), and although now recognized as biologically important, the HLA-C, DP, and DQ loci have historically been administratively dismissed in general organ allocation. Reporting requirements on the genetic typing of donors have now been expanded to include HLA-C, DP, and DQ so that these HLA molecules can also be considered for the purpose of organ allocation. Whereas improvements in kidney transplantation and immunosuppressive regimens have minimized some of the impact of matching, studies have demonstrated better renal allograft survival when the six primary alleles (A, B, and DR) are matched between donor and recipient, a so-called *six-antigen match* or *zero-antigen mismatch* (Fig. 49.8), and studies continue to show smaller but significant correlations between HLA mismatches and graft survival. HLA typing is not only important for the determination of MHC disparities between donors and recipients but is also critical for the avoidance of preformed HLA donor-specific antibodies that can exist in transplant recipients. Historically, MHC typing had been defined using serologic assays like the complement-dependent cytotoxicity (CDC) and microlymphocytotoxicity techniques that rely on antibodies to detect HLA antigens. These assays identify MHC antigens but suffer from low sensitivity and specificity, subjectivity in interpretation of results, and an inability to distinguish between closely related MHC molecules. Because of these logistical and performance limitations, they have been replaced by faster and more precise molecular techniques that define the actual nucleotide sequence of an individual's MHC.

Serologic typing via the CDC technique involved mixing patient lymphocytes with sera containing anti-HLA antibodies of known specificity, exogenous complement, and a vital dye (which is not taken up by intact cells). If a patient expressed an MHC matching the known anti-HLA antibody, the antibody would bind to patient lymphocytes, and added complement would lead to cell membrane disruption and visible uptake of vital dye under the microscope, confirming the MHC identity. However, as noted earlier, important antigen differences were not always identified this way, and the source of antibodies became more limiting as more relevant antigens were discovered. Thus, it has been supplanted by DNA-based molecular methods using polymerase chain reaction (PCR), including sequence-specific oligonucleotide (SSO), sequence-specific primers (SSPs), and sequence-based typing (SBT).

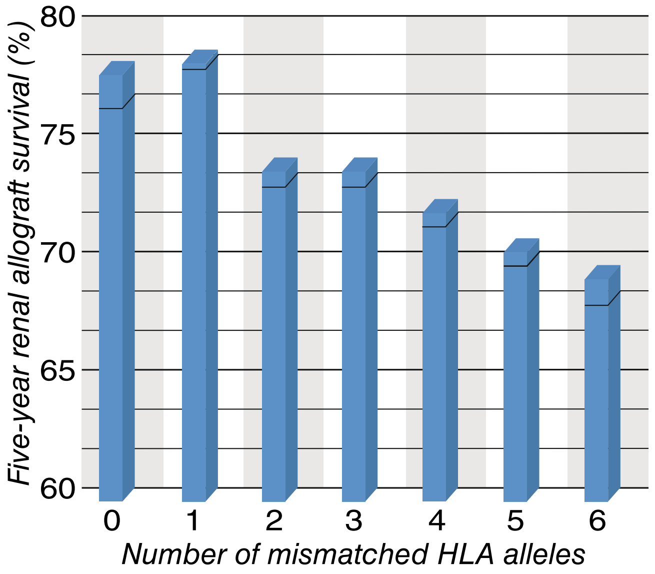

FIGURE 49.8 Influence of human leukocyte antigen *(HLA)* matching on renal allograft survival. Matching of HLA alleles between donor and recipient significantly improves renal allograft survival. The data are shown for deceased donor renal allografts stratified by number of matched HLA alleles. (Adapted from Abbas AK, Lichtman AH, Pillai S. *Cellular and Molecular Immunology*. 10th ed. Philadelphia: Saunders Elsevier; 2021.)

These advances in HLA typing have enhanced understanding of tissue compatibility between individuals, thus improving organ allocation—especially for recipients with preexisting HLA antibodies. Although the advent of PCR-based techniques transitioned tissue compatibility to more precise whole HLA antigen matching, rapidly advancing high-resolution molecular HLA typing techniques and next-generation sequencing have made it possible to view compatibility at the molecular and amino acid level. Molecular HLA typing data along with potent bioinformatics tools have combined to identify polymorphic amino acid clusters within whole HLA molecules that comprise the epitope specifically targeted by HLA-specific antibodies. These amino acid clusters, or "eplets," on or near the surface of the 3D HLA molecule can then be compared between donors and recipients as more precise determinants of compatibility compared with the whole HLA molecule or antigen. As such, HLA typing has evolved from crude measures of whole HLA antigen disparities between individuals to very high-resolution identification of the amino acids that form the epitopes on these large polymorphic HLA molecules that are specifically responsible for HLA compatibility and alloimmune outcomes (Fig. 49.9).

Cellular Components of the Acquired Immune System

The key cellular components of the immune system, T cells, B cells, and APCs, are hematopoietically derived and arise from a common progenitor stem cell. The development of the lymphoid system begins with pluripotent stem cells in the liver and bone marrow of the fetus. As the fetus matures, the bone marrow becomes the primary site of lymphopoiesis. B cells were named after the primary lymphoid organ that produces B cells in birds, the bursa of Fabricius. In humans and most other mammals, precursor B cells remain within the bone marrow as they mature and fully develop. Although precursor T cells also originate in the bone marrow, they soon migrate to the thymus, the primary site of T-cell maturation, where they become "educated" to self and acquire their specific cell surface receptors and the ability to generate effector function. Mature lymphocytes are then released from the primary lymphoid organs, the bone marrow and thymus, to populate the secondary lymphoid organs including lymph nodes, spleen, and gut as well as peripheral tissues. Each of these cells has a unique role in establishing the immune response. The highly coordinated network is regulated in part through the use of cytokines (Table 49.1).

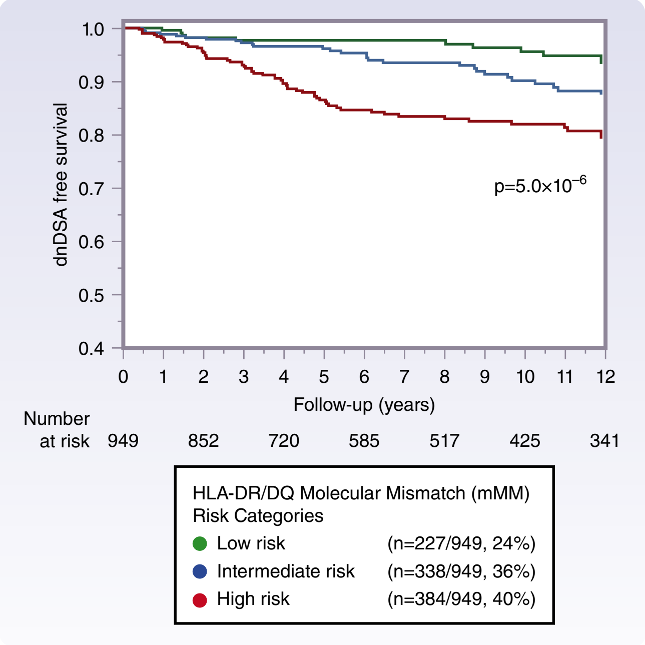

FIGURE 49.9 Impact of eplet mismatches on transplant outcomes. Analysis of eplets allows subcategorization of human leukocyte antigen (*HLA*)-DR and HLA-DQ mismatches between donor and recipient into those mismatches at low, intermediate, or high risk of allorejection. Use of these HLA-DR/DQ molecular mismatch risk categories accurately predicts the development of de novo donor-specific antibodies in renal transplant recipients. *dnDSA,* De novo donor-specific antibodies. (From Wiebe C, Balshaw R, Gibson IW, et al. A rational approach to guide cost-effective de novo donor-specific antibody surveillance with tacrolimus immunosuppression. *Am J Transplant.* 2023;23[12]:1882-1892.)

Both B and T cells are integral components of a highly specific response that must be prepared to recognize a seemingly endless array of pathogens. This is accomplished through a unique method that allows random generation of almost unlimited receptor specificity yet controls the ultimate product by eliminating or suppressing those that might react against self and perpetuate an autoimmune response. There are fundamental differences in the manner in which T and B cells recognize antigen. B cells are structured to respond to whole antigen and in response synthesize and secrete antibody that can interact with antigen at distant sites. T cells, on the other hand, are responsible for cell-mediated immunity and of necessity must interact with cells in the periphery to neutralize and eliminate foreign antigens. From the peripheral blood, T cells enter the lymph nodes or spleen through highly specialized regions in the postcapillary venules. Within the secondary lymphoid organ, T cells interact with specific APCs, where they receive the appropriate signals that in effect license them for effector function. They then exit the lymphoid tissues through the efferent lymph, eventually percolating through the thoracic duct and returning to the bloodstream. From there, they can return to the site of the immune response, where they encounter their specific antigen and carry out their predefined functions.

T-Cell Receptor

Considerable progress has been made in defining the mechanisms of T-cell maturation and the development of a functional TCR. The formation of the TCR is fundamental to the understanding of its function.[9] A central paradox of immunology for many years was how the immune system can encode millions of different antibodies and TCRs, given the fixed size of the human genome. This mystery was solved by Susumu Tonegawa, who was awarded the Nobel Prize in 1987 for his discovery of V(D)J recombination, the genetic mechanism that produces antibody and TCR diversity. The genetic locus encoding the α and β chains that comprise the TCR contains both a constant region (C) and a variable region that is assembled from a V genetic segment (with 52 options for the human β chain and ~70 for the α chain), a D genetic segment (2 options for the β chain and absent in the α chain), and a J segment (13 and 61 options, respectively). These V, D, and J segments are randomly assembled together by the RAG1 and RAG2 recombinases through a process of double-strand DNA breaks and nonhomologous DNA end joining, generating a "mixed-and-matched" recombined V(D)J segment that encodes the actual variable region of the TCR. Through this process of V(D)J recombination, a limited number of gene segments can generate millions of different TCR specificities (Fig. 49.10).

Regardless of the genes used, individual cells recombine to express a TCR with only a single specificity. These rearrangements

TABLE 49.1 Summary of Cytokines

CYTOKINE	SOURCE	PRINCIPAL CELLULAR TARGETS AND BIOLOGIC EFFECTS
Interleukin-1	Macrophages, endothelial cells, some epithelial cells	Endothelial cell: activation (inflammation, coagulation) Hypothalamus: fever Liver: synthesis of acute-phase proteins
Interleukin-2	T cells	T cells: proliferation, ↑ cytokine synthesis, survival, potentiates Fas-mediated apoptosis, promotes regulatory T-cell development NK cells: proliferation, activation B cells: proliferation, antibody synthesis (in vitro)
Interleukin-3	T cells	Immature hematopoietic progenitor cells: stimulates differentiation into myeloid lineage, proliferation of myeloid lineage cells
Interleukin-4	CD4+ T cells (Th2), mast cells	B cells: isotype switching to IgE T cells: Th2 differentiation, proliferation Macrophages: inhibition of IFN-γ–mediated activation Mast cells: stimulates proliferation
Interleukin-5	CD4+ T cells (Th2)	Eosinophils: activation, ↑ production B cells: proliferation, IgA production
Interleukin-6	Macrophages, endothelial cells, T cells	Liver: ↑ synthesis of acute-phase proteins B cells: proliferation of antibody-producing cells
Interleukin-7	Fibroblasts, bone marrow stromal cells	Immature hematopoietic progenitor cells: stimulates differentiation into lymphoid lineage T and B cells: important for survival during development as well as for T-cell memory
Tumor necrosis factor	Macrophages, T cells	Endothelial cells: activation (inflammation, coagulation) Neutrophils: activation Hypothalamus: fever Liver: ↑ synthesis of acute-phase proteins Muscle, fat: catabolism (cachexia) Many cell types: apoptosis
Interferon-γ	T cells (Th1, CD8+ T cells), NK cells	Macrophages: activation (increased microbicidal functions) B cells: isotype switching to IgG subclasses that facilitate complement fixation and opsonization T cells: Th1 differentiation Various cells: ↑ expression of class I and class II MHC, ↑ antigen processing and presentation to T cells
Type I interferons (IFN-α, IFN-β)	Macrophages: IFN-α Fibroblasts: IFN-β	All cells: stimulates antiviral activity including ↑ class I MHC expression NK cells: activation
Transforming growth factor-β	T cells, macrophages, other cell types	T cells: inhibition of proliferation and effector functions B cells: inhibition of proliferation, ↑ IgA production Macrophages: inhibits activation, stimulates angiogenic factors Fibroblasts: increased collagen synthesis
Lymphotoxin	T cells	Lymphoid organogenesis Neutrophils: increased recruitment and activation
BAFF (CD257)	Follicular dendritic cells, monocytes, B cells	B cells: survival and proliferation
APRIL (CD256)	T cells, follicular dendritic cells, monocytes	B cells: survival and proliferation
Interleukin-8	Lymphocytes, monocytes	Stimulates granulocyte activity Chemotactic activity
Interleukin-9	Activated Th2 lymphocytes	Enhances proliferation of T cells, mast cells
Interleukin-10	Macrophages, T cells (mainly regulatory T cells)	Macrophages and dendritic cells: inhibition of IL-12 production, stimulates expression of costimulatory molecules and class II MHC
Interleukin-11	Bone marrow stromal cells	Megakaryocytes: thrombopoiesis Liver: induces acute-phase proteins B cells: stimulates T-dependent antibody production
Interleukin-12	Macrophages, dendritic cells	T cells: Th1 differentiation NK and T cells: IFN-γ synthesis, increased cytotoxic activity
Interleukin-13	CD4+ T cells (Th2), NKT cells, mast cells	B cells: isotype switching to IgE Epithelial cells: increased mucus production Fibroblasts and macrophages: increased collagen synthesis
Interleukin-14	T cells, some B-cell tumors	B cells: enhances proliferation of activated B cells, stimulates Ig production
Interleukin-15	Macrophages, others	NK cells: proliferation T cells: proliferation (memory CD8+ T cells)

TABLE 49.1 Summary of Cytokines—cont'd

CYTOKINE	SOURCE	PRINCIPAL CELLULAR TARGETS AND BIOLOGIC EFFECTS
Interleukin-17	T cells	Endothelial cells: increased chemokine production Macrophages: increased chemokine/cytokine production Epithelial cells: GM-CSF and G-CSF production
Interleukin-18	Macrophages	NK and T cells: IFN-γ synthesis
Interleukin-21	Th2, Th17, Tfh	Drives development of Th17 and Tfh B cells: activation, proliferation, differentiation NK cells: functional maturation
Interleukin-22	Th17	Epithelial cells: production of defensins, increased barrier functions Promotes hepatocyte survival
Interleukin-23	Macrophages, dendritic cells	T cells: maintenance of IL-17–producing T cells
Interleukin-27	Macrophages, dendritic cells	T cells: inhibits production of IL-17/Th17 cells, promotes Th1 differentiation NK cells: IFN-γ synthesis
Interleukin-33	Endothelial cells, smooth muscle cells, keratinocytes, fibroblasts	Th2 development and cytokine production

APRIL, A proliferation-inducing ligand; *BAFF,* B cell–activating factor; *G-CSF,* granulocyte-colony stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *IFN,* interferon; *Ig,* immunoglobulin; *IL,* interleukin; *MHC,* major histocompatibility complex; *NK,* natural killer; *NKT,* natural killer T cell; *Tfh,* T follicular helper.

FIGURE 49.10 Diversity of antigen receptor genes. The variable regions of T-cell receptors and immunoglobulins are both produced by the genetic mechanism of V(D)J recombination. Several enzymes found only in lymphocytes (such as the RAG recombinases) mediate this special kind of nonhomologous DNA recombination event. Combinations of different V, D, and J gene segments from the germline DNA are derived, with the addition or removal of nucleotides at the joints. This process generates the mRNA of millions of different recombined antigen receptors. (Adapted from Abbas AK, Lichtman AH, Pillai S. *Cellular and Molecular Immunology*. 10th ed. Philadelphia: Saunders Elsevier; 2021.)

occur randomly and can theoretically produce 10^{10} different TCRs; however, 10^{10} T cells would weigh 500 kg and cannot all be contained in the human body. Based on computational models of homeostasis of multiclonal populations of T cells, it is estimated that approximately 10^9 naïve T-cell clonotypes (i.e., T cells with the same TCR specificity) are present at any point in time.[10] As a result, the frequency of naïve T cells available to respond to any given pathogen is relatively small, estimated to be between 1 in 200,000 and 1 in 500,000. These developing T cells also express both CD4 and CD8, accessory molecules that strengthen TCR binding to MHC. These accessory molecules further increase the binding repertoire of the population to include either class I or class II MHC molecules. If the process of T-cell maturation ended at this stage, there would be a host of T cells that could recognize self MHC–peptide complexes, resulting in an uncontrolled, global autoimmune response. To avoid the release of autoreactive T cells, developing cells undergo a process after recombination known as *positive and negative thymic selection* (Fig. 49.11).[11] Cells initially interact with the MHC-expressing cortical thymic epithelium, which produces hormones (thymopoietin and thymosin) as well as cytokines (e.g., interleukin [IL]-7) that are critical to T-cell development. If binding does not occur to self MHC, those cells are useless to the individual (e.g., they cannot bind self cells to assess for infection), and they are permitted to die by neglect through apoptosis, a process called *positive selection.* Thus, positive selection ensures that T cells are restricted to self MHC. Cells surviving positive selection then move to the thymic medulla and normally eventually lose either CD4 or CD8. If binding to self MHC in the medulla occurs with an unacceptably high affinity, there is an active process whereby death-promoting signals are delivered and programmed cell death is initiated, a process termed *negative selection.* Negative selection stands in contrast to the death that occurs by neglect when immature lymphocytes are not positively selected. Negative selection of T cells in the thymus is a form of central tolerance in the immune system, resulting in the deletion of a pathogenic autoreactive T-cell repertoire. Another possible, although less common, outcome of a high-affinity interaction with self peptide–MHC is the development of a regulatory T-cell (Treg) phenotype. The precise nature of this affinity threshold remains a matter of intense investigation and involves interaction with hematopoietic cells that reside in the thymus as well as medullary thymic epithelial cells. These thymically derived "natural" Tregs emerge from the thymus and are involved in the suppression of autoreactive T cells in the periphery, which is discussed later.

The only cells released into the periphery are those that can both bind self MHC and avoid activation by self-antigens.

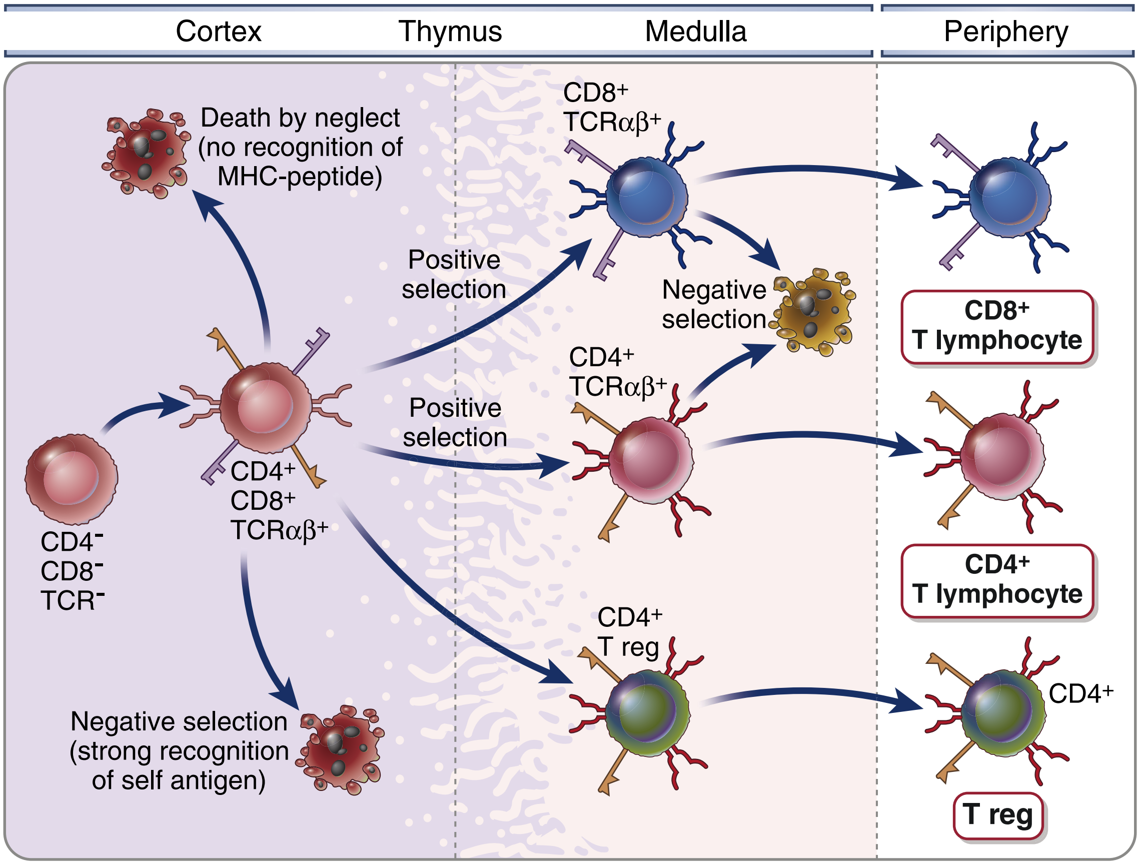

FIGURE 49.11 T-cell maturation in the thymus. Initially, bone marrow–derived T-cell precursors arrive in the thymic cortex lacking CD4, CD8, or a T-cell receptor *(TCR)* and are referred to as *double negative.* In the thymic cortex, these cells begin to express TCRs and the CD4 and CD8 coreceptors. Positive selection promotes the survival of T cells bearing TCR that can bind to self-major histocompatibility complex *(MHC)*, whereas negative selection promotes the deletion of T cells bearing autoreactive TCR. The T cells progress through a double-positive (expressing both CD4 and CD8) and eventually a single-positive stage, where they ultimately express only CD4 or CD8, depending on which class of MHC they restrict to. (Adapted from Abbas AK, Lichtman AH, Pillai S. *Cellular and Molecular Immunology.* 10th ed. Philadelphia: Saunders Elsevier; 2021.)

Whereas T cells are restricted to bind self MHC–peptide complexes without activation, the selection process does not consider foreign MHC. Thus, by random chance, some cells with appropriate affinity for self MHC survive and have inappropriately high affinity for the MHC molecules of other individuals. In the setting of transplantation, these recipient T cells are able to recognize donor MHC–peptide complexes because sufficient conserved motifs are shared between donor and self MHC molecules. However, because donor MHC was not present during the thymic education process, the binding of donor MHC by an "alloreactive" T cell leads to activation, and rejection ensues. The precursor frequency, or the number of alloreactive T cells, is much higher than the 1 in 200,000 or 1 in 500,000 T cells available to react toward any given antigen. Because T cells are selected to bind self MHC, the frequency specific for a similar, nonself MHC (i.e., alloreactive) is estimated to be between 1% and 10% of all T cells.[12]

In addition to thymic selection, it is now clear that mechanisms exist for peripheral modification of the T-cell repertoire, so-called *peripheral mechanisms of tolerance*. Many of these mechanisms are in place for removal of T cells after an immune response and downregulation of activated clones. CD95, a molecule known as *Fas,* is a member of the TNF receptor superfamily and is expressed on activated T cells. Under appropriate conditions, binding of this molecule to its ligand, CD178, promotes programmed cell death of a cohort of activated T cells. This method is dependent on TCR binding and the activation state of the T cell. Complementing this deletional method to TCR repertoire control are nondeletional mechanisms that selectively anergize (make unreactive) specific T-cell clones. In addition to signaling through the TCR complex, T cells require additional costimulatory signals (described in detail later). TCR binding leads to T-cell activation only if the costimulatory signals are present, generally delivered by APCs. In the absence of costimulation, the cell remains unable to proceed toward activation and in some circumstances becomes refractory to activation even with the appropriate signals. Thus, TCR binding that occurs to self in the absence of appropriate antigen presentation or active inflammation results in an aborted activation and prevents self-reactivity.

T-Cell Activation

T-cell activation is a sophisticated series of events that has only recently been more fully described, leading to the emergence of the three-signal hypothesis. Most naïve T cells require three unique signals for activation: "signal 1" mediated by TCR binding to cognate antigen presented by self-MHC, "signal 2" enacted by engagement of the T cell with costimulatory receptors (to be described later), and "signal 3" effectuated by cytokines that promote and shape the development of the subsequent immune response. Most existing immunosuppression drugs act through the disruption of one or more of these signals required for T-cell activation.

The exquisite regulation of T-cell activation is first guided by the specificity of signal 1, the TCR binding to cognate antigen presented by self-MHC. Because the number of potential antigens is high and the likelihood is that self-antigens vary minimally from foreign antigens, the nature of the TCR-binding event has evolved such that a single interaction with an MHC molecule is not sufficient to cause activation. In fact, a T cell must register a signal from approximately 8000 TCR-ligand interactions with the same antigen before a threshold of activation is reached. Each event results in the internalization of the TCR. Because resting T cells have low TCR density, sequential binding and internalization during several hours are required. Transient encounters are not sufficient. This threshold is reduced considerably by appropriate costimulation signals (detailed later).

Most TCRs are heterodimers composed of two transmembrane polypeptide chains, α and β. The αβ-TCR is noncovalently associated with several other transmembrane signaling proteins, including CD3 (composed of three separate chains, γ, δ, and ε) and ζ chain molecules as well as the appropriate accessory molecule from the T cell, either CD4 or CD8, which associates with its respective MHC molecule. Together, these proteins are known as the *TCR complex*. When the TCR is bound to an MHC molecule and the proper configuration of accessory molecules stabilizes its binding, a signal is initiated by intracytoplasmic protein tyrosine kinases (Fig. 49.12). These protein tyrosine kinases include p56lck (on CD4 or CD8), p59Fyn, and ZAP-70, the last two of which are associated with CD3. Repetitive binding signals combined with the appropriate secondary costimulation eventually activate phospholipase-γ1, which in turn hydrolyzes the membrane lipid phosphatidylinositol bisphosphate, thereby releasing inositol trisphosphate and diacylglycerol. Inositol trisphosphate binds to the endoplasmic reticulum, causing a release of calcium that induces calmodulin to bind to and activate calcineurin. Calcineurin dephosphorylates the critical cytokine transcription factor nuclear factor of activated T cells (NFAT), prompting it, with the transcription factor nuclear factor κB (NF-κB), to initiate transcription of cytokines including IL-2 and its receptor. Resting T cells express only low levels of the IL-2 receptor (CD25), but with activation, IL-2R expression is increased. As the activated T cell begins to produce IL-2 secondary to events initiated by TCR activation, the cytokine begins to work in both autocrine and paracrine fashions, potentiating diacylglycerol activation of protein kinase C. Protein kinase C is important in activating many gene regulatory steps critical for cell division. This effect, however, is restricted only to T cells that have undergone activation after encountering their specific antigen leading to IL-2R expression. Thus, the process limits proliferation and expansion to only those clones specific for the offending antigen. As the antigenic stimulus is removed, IL-2R density decreases and the TCR complex is reexpressed on the cell surface. There is a negative feedback system between the TCR and the IL-2R, resulting in a highly regulated and efficient system that is reactive only in the presence of antigen and ceases to function once antigen is removed. Not surprisingly, many of these steps in T-cell activation have been targeted in the development of immunosuppressive agents. These are discussed in detail in a subsequent section of this chapter.

Costimulation

Recognition of the antigenic peptide–MHC complex through TCR binding is usually not sufficient alone to generate a response in a naïve T cell. Additional signals through so-called costimulatory pathways are required for optimal T-cell activation.[13,14] In fact, receipt of TCR complex signaling, often referred to as signal 1, in the absence of costimulation, or signal 2, not only fails to achieve activation but also can lead to a state of inaction or anergy (Fig. 49.13). An anergic T cell is rendered unable to respond even if given both of the appropriate stimuli.[15] This characteristic of the immune system is thought to be one of the major mechanisms in tolerance to self-antigens in the periphery, crucial in the prevention of autoimmunity. Researchers have exploited this discovery using antibodies or receptor fusion proteins

FIGURE 49.12 T-cell activation. On antigen recognition, there is a clustering of T-cell receptor *(TCR)* complexes and coreceptors that initiates a cascade of signaling events within the T cell. Tyrosine kinases associated with the coreceptors (e.g., Lck) phosphorylate CD3 and the ζ chain (A). The ζ chain association protein kinase (ZAP-70) subsequently associates with these regions and becomes activated. ZAP-70 phosphorylates various adaptor molecules, such as LAT (B). These adaptors become docking sites for other enzymes such as PLCγ1 and GDP-GTP exchange factors that ultimately activate downstream MAP kinase pathways (C). PLCγ1 activation specifically produces a rapid increase in cytosolic free calcium, which in turn activates the calcium-calmodulin–dependent phosphatase calcineurin. Calcineurin dephosphorylates cytoplasmic NFAT, which then translocates into the nucleus and serves as a critical transcription factor promoting the expression of various genes involved in proliferation and T-cell responses. (Adapted from Abbas AK, Lichtman AH, Pillai S. *Cellular and Molecular Immunology*. 10th ed. Philadelphia: Saunders Elsevier; 2021.)

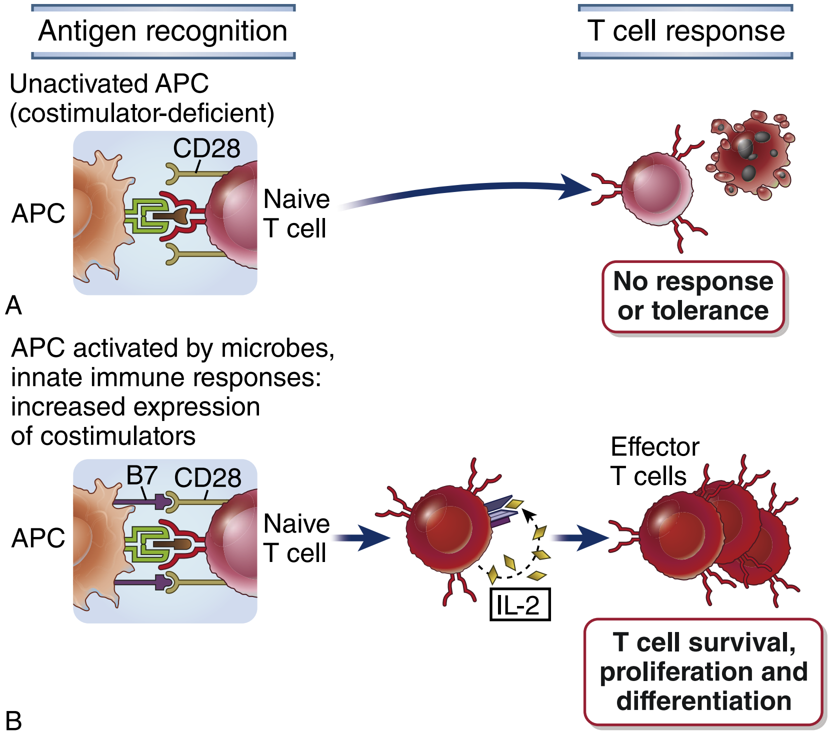

FIGURE 49.13 T-cell costimulation. Naïve T cells require multiple signals for efficient activation. (A) Signal 1 occurs when the T-cell receptor (TCR) recognizes its putative major histocompatibility complex–peptide combination. In the absence of any additional signals, there is an aborted response or anergy, a state in which the cell is no longer available for stimulation. (B) TCR signaling in conjunction with signals received through costimulatory molecules (e.g., B7 molecules), signal 2, promotes effective T-cell activation and function. *APC,* Antigen-presenting cell; *IL-2,* interleukin-2. designed to block interactions between key costimulatory molecules at the time of antigen exposure. Much of the research to date has focused on the interactions of two costimulatory pathways: the CD28/B7 pathway (Ig-like superfamily members) and CD40/CD154 pathway (TNF/TNFR superfamily members). However, many additional pairings within these same families and others have been found to have distinct roles in costimulatory function (Table 49.2).

CD28, present on T cells, and the B7 molecules CD80 and CD86 on APCs were among the first costimulatory molecules to be described. Ligation of CD28 is necessary for optimal IL-2 production and can lead to the production of additional cytokines (e.g., IL-4 and IL-8) and chemokines (e.g., "regulated upon activation, normal T-cell expressed and presumably secreted" ([RANTES]) as well as protect T cells from activation-induced apoptosis through the upregulation of antiapoptotic factors such as Bcl-X_L and Bcl-2. CD28 is expressed constitutively on most T cells, whereas the expression of CD80 and CD86 is largely restricted to professional APCs, such as dendritic cells, monocytes, and macrophages. The kinetics of CD80/CD86 expression is complex, but they are typically increased with the induction of the immune response. Another ligand for CD80 and CD86 is CTLA-4 (CD152). This molecule is upregulated and expressed on the surface of T cells after activation, and it binds CD80/CD86 with 10 to 20 times greater affinity than CD28. CTLA-4 has been shown to have a negative regulatory effect on T-cell activation and proliferation, an observation supported by the fact that CTLA-4–deficient mice develop a lethal lymphoproliferative disorder. The negative regulatory effect of CTLA-4 is mediated through both cell intrinsic activation of intracellular phosphatases and a cell extrinsic mechanism in which CTLA-4 binding actually removes CD80/CD86 from the surface of the APC, thereby limiting the availability of ligands for CD28 costimulation. The therapeutic potential of costimulation blockade was first made apparent through the development of CTLA-4–Ig, an engineered fusion protein composed of the extracellular portion of the CTLA-4 molecule and a portion of the human Ig molecule. This compound binds CD80 and CD86 and prevents costimulation through CD28. Several clinical trials in autoimmunity have demonstrated the efficacy of CTLA-4–Ig (abatacept). More recently, a higher-affinity, second-generation version, belatacept, has been tested with success as a replacement for calcineurin inhibitors (CNIs) and was approved in 2011 for kidney transplant recipients.[16,17]

Closely related to the CD28/B7 pathway is the CD40/CD154 (CD40L) pathway. Evidence for the crucial role of the CD40/CD154 pathway in the immune response came to light after the observation that hyper-IgM syndrome results from a mutational defect in the gene encoding CD154. In addition to defects in the generation of T-cell–dependent antibody responses, patients with hyper-IgM syndrome also have defects in T-cell–mediated immune responses. CD40 is a cell surface molecule expressed on endothelium, B cells, dendritic cells, and other APCs. Its ligand, CD154, is primarily found on activated T cells. Upregulation of CD154 after TCR signaling allows signals to be sent to the APC through CD40; in particular, it is a critical signal for B-cell activation and proliferation. CD40 binding is required for APCs to stimulate a cytotoxic T-cell response. It leads to the release of

TABLE 49.2 **Costimulatory Molecules**

RECEPTOR	DISTRIBUTION	LIGAND	DISTRIBUTION	PRINCIPAL EFFECTS AND FUNCTIONS
CD28	T cells	CD80/CD86	Activated APCs	Lowers the threshold for T-cell activation Promotes survival, ↑ antiapoptotic factors Promotes Th1 phenotype
CD40	Dendritic cells, B cells, macrophages, endothelial cells	CD154	T cells, soluble platelets	Induces CD80/CD86 expression on APCs
CD27	T cells, NK cells, B cells	CD70	Thymic epithelium, activated T cells, activated B cells, mature dendritic cells	Enhances T-cell proliferation and survival Acts after CD28 to sustain effector T-cell survival Influences secondary responses more than primary Promotes B-cell differentiation and memory formation
CD30	Activated T cells, activated B cells	CD153	B cells, activated T cells	Maintains survival of primed and memory T cells Promotes Th2 > Th1
CD95 (Fas)	T cells, B cells, APCs, stromal cells	CD178 (FasL)	T cells, APCs, stromal cells	Involved in peripheral T-cell homeostasis through “fratricide,” may deliver costimulatory signal
CD134 (OX40)	Activated T cells CD4+ > CD8+	CD252 (OX40L)	Activated T cells, mature dendritic cells, activated B cells	Important for CD4+ T-cell expansion and survival ↑ Antiapoptotic factors Functions after CD28 to sustain CD4+ T-cell survival Enhances cytokine production Augments effector and memory CD4+ T-cell function Promotes Th2 > Th1
CD137 (4-1BB)	Activated T cells CD8+ > CD4+ Monocytes, follicular dendritic cells, NK cells	4-1BBL	Mature dendritic cells, activated B cells, activated macrophages	Sustains rather than initiates CD8+ T-cell responses Functions after CD28 to sustain T-cell survival Important in antiviral immunity Promotes CD8+ effector function and cell survival
CD152 (CTLA-4)	Activated T cells	CD80/CD86	Activated APCs	Higher affinity for CD80/CD86 than CD28, inhibits T-cell response
HVEM	T cells, monocytes, immature dendritic cells	CD258 (LIGHT)	Activated lymphocytes, immature dendritic cells, NK cells	Augments T-cell responses, CD8+ > CD4+ Promotes dendritic cell maturation
		CD272 (BTLA)	Activated T cells, B cells, dendritic cells	Negative costimulator, inhibits IL-2 production BTLA remains expressed on Th1 but not Th2
		CD160	NK cells, cytolytic CD8+ T cells, γδ T cells	Negative regulator of CD4+ T-cell activation Inhibits proliferation and cytokine production
CD265 (RANK)	Dendritic cells	CD254 (TRANCE)	Activated T cells CD4+ > CD8+	Enhances dendritic cell survival, upregulates Bcl-xl, possibly enhances IFN-γ production
CD279 (PD-1)	T cells	CD274 (PD-L1)	T cells, B cells, APCs, some parenchymal cells	Inhibits activation, proliferation, and acquisition of effector cell function Th1 > Th2
		CD273 (PD-L2)	Dendritic cells, macrophages	Inhibits activation, proliferation, and acquisition of effector cell function Th2 . Th1
CD278 (ICOS)	Activated T cells, memory T cells	CD275 (ICOSL)	Dendritic cells, B cells, macrophages	Promotes survival and expansion of effector T cells, possibly promotes Th2 responses
GITR	Tregs, CD8+ T cells, B cells, macrophages	GITRL	B cells, dendritic cells, macrophages, endothelial cells	Marker for Tregs, allows proliferation of Tregs Promotes T-cell proliferation and cytokine production Negative regulator for NK function

APC, Antigen-presenting cell; *BTLA,* B and T lymphocyte–associated; *CTLA,* cytotoxic T lymphocyte–associated; *GITR,* glucocorticoid-induced tumor necrosis factor receptor; *GITRL,* glucocorticoid-inducted tumor necrosis factor receptor ligand; *HVEM,* herpes virus entry mediator; *ICOS,* inducible costimulator; *ICOSL,* inducible costimulator ligand; *NK,* natural killer; *PD,* programmed death; *RANK,* receptor activator of NFκB; *Treg,* regulatory T cell.

activating cytokines, particularly IL-12, and the upregulation of B7 molecules. It also initiates innate functions of APCs, including nitric oxide synthesis and phagocytosis. Interestingly, CD154 is also released in soluble form by activated platelets. Thus, sites of trauma that attract activated platelets simultaneously recruit the ligand required to activate tissue-based APCs, providing a link between innate and acquired immunity. Antibody preparations against CD154 have shown great promise in experimental models, but initial clinical trials were halted because of concern for unexpected thrombotic complications. There continues to be hope that anti-CD154 antibodies that bind distinct epitopes, Fc-silent domain antibodies devoid of cross-linking abilities, or antibodies directed toward CD40 may circumvent this issue (see “Immunosuppression” section).

Since earlier investigations, multiple other pairings of molecules have been characterized and shown to demonstrate costimulatory or coinhibitory activity. It is the sum of these positive costimulatory and negative coinhibitory signals that shapes the character and magnitude of the T-cell response.[18] CD278 (inducible costimulator, or ICOS) is a CD28 superfamily expressed on activated T cells, and its ligand, CD275 (ICOSL or B7-H2), is expressed on APCs. Unlike CD28, ICOS is not present on naïve T cells, but instead expression is upregulated after T-cell activation and persists on memory T cells. ICOS can function to boost activation of effector T cells in general but in particular plays a critical role in the function of T follicular helper (Tfh) cells, a specialized CD4+ T-cell subset involved in the germinal center reaction and generation of class-switched antibody. Another member of the CD28 superfamily, programmed cell death 1 (PD-1) (CD279), and its ligands PD-L1 (CD274) and PD-L2 (CD273), both B7 family members, have been shown to be involved in negative regulation of cellular immunity. More recently, coinhibitory molecules PD-1H (also known as *VISTA* for V domain Ig suppressor of T-cell activation) and B- and T-lymphocyte–associated (BTLA) have joined this list. Several members of the TNF/TNFR superfamily have been shown to play important roles in T-cell costimulation. These include CD134/CD252 (OX40/OX40L), CD137/CD137L (4-1BB/4-1BBL), CD27/CD70, CD95/CD178 (Fas/FasL), CD30/CD153, receptor activator of NF-κB/TNF-related activation-induced cytokines (RANK/TRANCE), and others. Furthermore, members of the CD2 family function in both costimulatory (i.e., CD2) and coinhibitory (i.e., 2B4) roles during the execution of an alloimmune response. Finally, the T cell–Ig mucin-like family of molecules has been shown to play important coinhibitory roles during alloimmunity, both on effector cells and on Tregs.

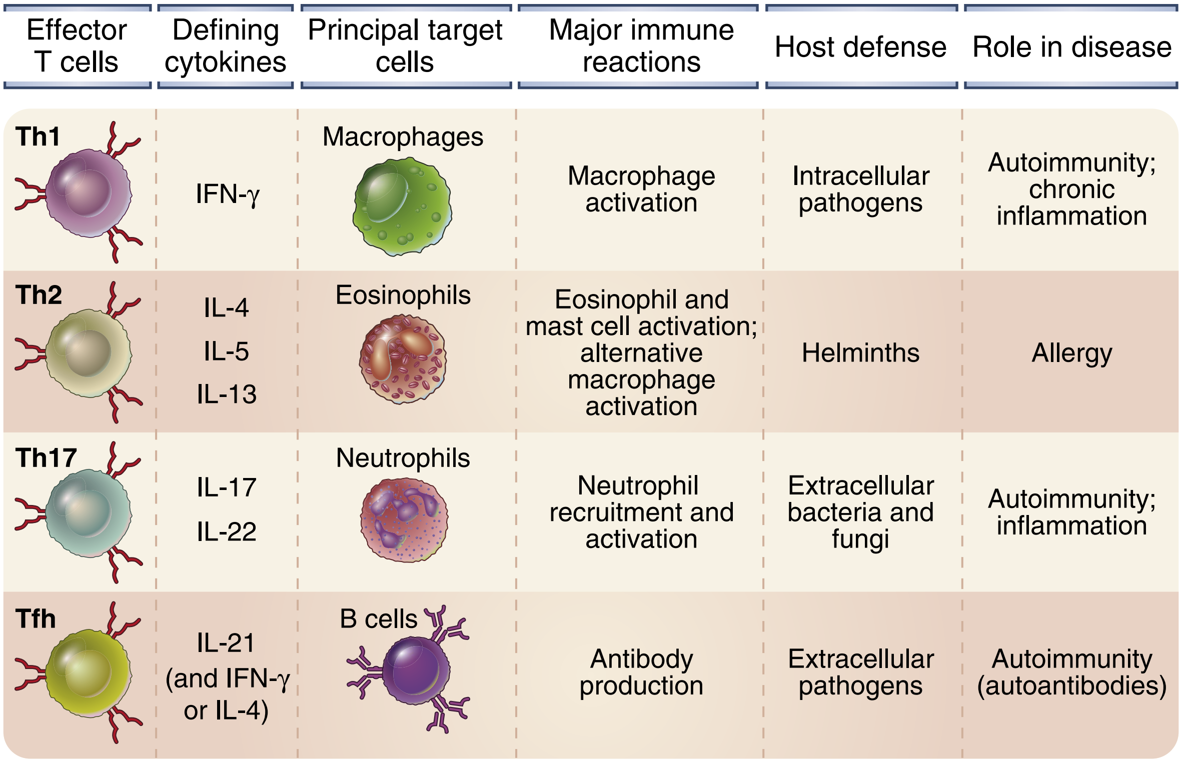
In addition to the multitude of costimulatory molecules, many other adhesion molecules expressed on the cell surface (intercellular adhesion molecules, selectins, integrins) control the movement of immune cells through the body, regulate their trafficking to specific areas of inflammation, and nonspecifically strengthen the TCR-MHC binding interaction. They differ from costimulation molecules in that they enhance the interaction of the T cell with other cell types and antigen without directly influencing the quality of the TCR response. There are two main families of cellular adhesion molecules within the immune system: the selectins and the integrins. The selectin family of adhesion molecules is responsible for "rolling"—the initial attachment of leukocytes to vascular endothelial cells at sites of tissue injury and inflammation before their firm adhesion (mediated by integrin binding). The selectin family of proteins is composed of three closely related molecules, each having differential expression on immune cells: L-selectin is expressed on leukocytes, P-selectin is expressed on platelets, and E-selectin is expressed on endothelium. Structurally, all selectins share an amino-terminal lectin domain that interacts with a carbohydrate ligand, an epidermal growth factor–like domain, and two to nine short repeating units that share homology with sequences found in some complement-binding proteins. In contrast to most other adhesion molecules that also possess some signaling or costimulatory functionality, selectins function solely to facilitate leukocyte binding to vascular endothelium. This selectin-mediated loose binding is converted into tight adhesion after activation of leukocyte integrins. Integrins are transmembrane receptors that serve as bridges for cell-cell as well as for cell–extracellular matrix interactions. Many are expressed constitutively on cells of the immune system (i.e., leukocyte function antigen 1) but on sensing inflammatory cytokine or chemokine signals, such as IL-8, are induced to change conformation that results in higher avidity interaction with integrin ligands, resulting in leukocyte extravasation into inflamed tissue. Both selectins and integrins are potential therapeutic targets to inhibit access of donor-reactive T cells into the allograft and weaken proimmune interactions.

T-Cell Effector Functions

During thymic education, most T cells initially express both CD4 and CD8 molecules, but subsequently, T cells become either CD4+ or CD8+, depending on which MHC class they restrict to. Thus, these accessory molecules govern which type of MHC and, by extension, which types of cells a given T cell can interact with and evaluate. Because there is nearly ubiquitous expression of class I MHC, all cell types are surveyed. These class I molecules display peptides that are generated within the cell (e.g., peptides from normal cellular processes or from internal viral replication). T cells responsible for inspecting all cells express the accessory molecule CD8, which in turn binds to class I and specifically stabilizes a TCR interaction with a class I–presented antigen. Thus, CD8+ T cells evaluate most cell types and mediate destruction of altered cells. Appropriately, they have been termed *cytotoxic T cells.*

APCs are the predominant cell type that expresses class II MHC molecules in addition to class I. Class II molecules display peptides that have been sampled from surrounding extracellular spaces through phagocytosis and thus usually represent the presentation of newly acquired antigen. Cells initiating an immune response need to have access to this newly processed antigen. CD4 binds class II MHC and stabilizes the interaction of the TCR with the class II–peptide complex. Thus, under physiologic conditions, CD4+ T cells are first alerted to an invasion of the body by hematopoietically derived APCs that present their newly acquired antigen in the form of processed peptide in a class II molecule. As a consequence of their MHC restriction, these subpopulations of T cells have several different functions. CD4+ T cells typically contribute to the response in a helper or regulatory role, whereas CD8+ T cells are much more likely to play a part in cell elimination through cytotoxic functions.

After activation, CD4+ T cells initially play a critical role in the expansion of the immune response. After encountering an APC that expresses the specific antigenic peptide–MHC class II pairing, the CD4+ T cell can then signal back to the APC to promote factors that allow CD8+ T-cell activation. This process is accomplished by expression of specific costimulatory molecules and the release of certain cytokines. This licensing of CD8+ T cells for cytotoxic function is a key step within the immune response. This describes in part how CD4+ T cells become helper cells. More recently, there has been further elucidation of their cellular differentiation into several well-defined Th subsets, including Th1, Th2, Th17, and Tfh cells, which are largely defined on the basis of the distinct transcription factors they express and the cytokines they elaborate (Fig. 49.14). The main cytokine driving the differentiation of Th1 cells is IL-12, and mature Th1 cells mediate effector function through the release of IFN-γ and TNF. The predominant role of IFN-γ is to enhance macrophage function and activity as well as to promote cell-mediated immunity. Activated macrophages then proceed to ingest and to kill invading microbes, and at the same time, the acquired immune system is directed to produce antibodies that promote opsonization, thereby enhancing the overall process. Th2 cell differentiation, in contrast, is driven by the presence of IL-4 and results in release of IL-4, IL-5, IL-10, and IL-13, which ultimately inhibit macrophage activation and promote IgE production and eosinophil activation.



Effector T cells	Defining cytokines	Principal target cells	Major immune reactions	Host defense	Role in disease
Th1	IFN-γ	Macrophages	Macrophage activation	Intracellular pathogens	Autoimmunity; chronic inflammation
Th2	IL-4 IL-5 IL-13	Eosinophils	Eosinophil and mast cell activation; alternative macrophage activation	Helminths	Allergy
Th17	IL-17 IL-22	Neutrophils	Neutrophil recruitment and activation	Extracellular bacteria and fungi	Autoimmunity; inflammation
Tfh	IL-21 (and IFN-γ or IL-4)	B cells	Antibody production	Extracellular pathogens	Autoimmunity (autoantibodies)

FIGURE 49.14 T-cell subsets. Naïve CD4+ T cells may differentiate into distinct subsets of effector cells in response to antigen, costimulatory, or coinhibitory signals and cytokines. Th1 cells produce interferon-γ *(IFN-γ)*, which activates macrophages to kill intracellular microbes. Th2 cells produce cytokines (interleukin *[IL]*-4, IL-5, and others) that stimulate immunoglobulin E production and activate eosinophils in response to parasitic infection. Th17 cells secrete IL-17 and IL-22; they play an important role in responses to fungi and contribute to several autoimmune inflammatory diseases. Tfh cells produce IL-21 and provide help to B cells for antibody production. (Adapted from Abbas AK, Lichtman AH, Pillai S. *Cellular and Molecular Immunology*. 10th ed. Philadelphia: Saunders Elsevier; 2021.)

Th17 cells are an inflammatory CD4+ subset that plays a major role in the protective immune response against fungal pathogens and extracellular bacteria. Th17 cells are generated in the presence of transforming growth factor-β (TGF-β) and IL-6 and are potent secretors of the inflammatory cytokines IL-17 and IL-23. Interestingly, in addition to their role in protective immunity, Th17 cells have been associated with several autoimmune diseases, including multiple sclerosis, rheumatoid arthritis, and psoriasis, and several immunomodulatory therapies are being developed to impair their activity in these patients. Finally, Tfh cells are ICOS+ PD-1+ cells that home to lymphoid germinal centers by virtue of their expression of the chemokine receptor CXCR5, where they provide help for the generation of class-switched, high-affinity IgG responses. Tfh cells provide this help in the form of CD154 expression and the secretion of IL-21.

An important feature of these CD4+ Th cells is the ability of one subset to regulate the activity of the other. For example, IL-10 produced by Th2 cells and Tregs negatively regulates transcription of IFN-γ mRNA. Thus, the initial steps in differentiation depend greatly on the surrounding immunologic milieu, which ultimately influences the character of the immune response. This unique cytokine environment that shapes developing immune responses constitutes “signal 3” of the three-signal hypothesis of T-cell activation. Furthermore, more recent fate mapping studies have revealed a high degree of plasticity between Th subsets, demonstrating that cells of one Th subset can, under certain conditions, transdifferentiate into another Th subset.

Another subset of CD4+ T cells that has been described to play a critical role in the ability of the immune system to temper its response is the Treg population. Tregs suppress immune responses either through direct cell-cell contact with effector cells or indirectly through their interaction with APCs. These cells not only have the ability to suppress cytokines, adhesion molecules, and costimulatory signals but are also able to focus this response by expression of integrins, which allows Tregs to home to the location of immune engagement. The most extensively studied population of Tregs are those CD4+ T cells that express the transcription factor FoxP3, the majority of which also express CD25 (the high-affinity α chain of the IL-2 receptor).[19] CD4+/CD25+/Foxp3+ Tregs play a critical role in maintaining peripheral self-tolerance and in preventing pathologic inflammation; indeed, both mice and humans that lack a functional Foxp3 molecule develop severe systemic autoimmunity. Thus, CD4+/CD25+/Foxp3+ T cells have been the target of numerous attempts to alter immune function and are being tested in clinical trials of cellular immunotherapy to control graft rejection after transplantation and to mitigate autoimmunity. Foxp3+ Tregs develop during T-cell thymic development after recognition of self-antigen in the thymus (with signal strength that is not sufficient to induce negative selection). These so-called *natural Tregs* (also termed *thymic Tregs*) express a TCR repertoire distinct from that of conventional T cells and are important for maintaining immune homeostasis and preventing autoimmunity. However, Foxp3+ Tregs can also develop extrathymically during the course of an immune response, and studies have shown that these cells are elicited by stimulation with low-dose antigen or under conditions of limited CD154 costimulation. These so-called *induced Tregs* (also termed *peripheral Tregs*) are highly specific for the antigen by which they were elicited and, thus, may be more potent suppressors of autoimmunity and transplant rejection when used as cellular immunotherapy.

Unlike CD4+ T cells, CD8+ T cells function primarily to eliminate infected or defective cells. As mentioned before, licensing occurs through APC interactions, and subsequent cell killing occurs by either a calcium-dependent secretory mechanism or a calcium-independent mechanism that requires direct cell contact. In the calcium-dependent mechanism, the rise in intracellular calcium after activation triggers exocytosis of cytolytic granules. These granules contain a lytic protein called *perforin* and serine proteases called *granzymes*. Perforin polymerization creates defects in the target cell's membrane, allowing granzyme activity to lyse the cell. In the absence of calcium, T cells can induce apoptosis of a target cell through a Fas-dependent mechanism. It occurs when surface CD95 (Fas) is bound by its ligand CD178 (FasL). Cytotoxic T cells upregulate CD178 on activation. This, in turn, binds CD95 on target cells, resulting in programmed cell death.

Cytokines

Cell surface receptors provide an interface through which adjacent cells can transfer signals vital to the immune response. Whereas this cell-to-cell contact is a critical component of cellular communication, soluble mediators are also used extensively to accomplish similar tasks. These polypeptides, termed *cytokines,* are critical to the development and function of both the innate and acquired immune processes. The action of cytokines, also known as *interleukins* (see Table 49.1), may be autocrine (on the same cell) or paracrine (on adjacent cells), but is usually not endocrine. They are released by multiple cell types and may function to activate, suppress, or even amplify the response of adjacent cells. The prototypical cytokine of T-cell activation is IL-2. Once a given T cell encounters its specific antigen in the setting of appropriate costimulation, it will subsequently produce and release IL-2 as well as other cytokines that will influence any cell within its vicinity. As mentioned before, Th cellular subsets are differentiated on the basis of the pattern of cytokine expression. Th1 cells, which mediate cytotoxic responses such as delayed-type hypersensitivity, express IL-2, IL-12, IL-15, and IFN-γ. Th2 cells support the development of humoral or eosinophilic responses and consequently express IL-4, IL-5, IL-10, and IL-13. Th17 cells, a more recently described subset, are distinguished by their production of IL-17, IL-21, and IL-22.

Cytokine receptors are now known to function through Janus kinase (JAK) signal transduction proteins. They convey signals to signal transducers and activators of transcriptions (STATs), DNA-binding proteins that translocate to the nucleus to influence gene transcription. As is the case with most of the immune response, this pathway is tightly regulated. For example, suppressors of cytokine signaling proteins act in a negative feedback loop to inhibit STAT phosphorylation by binding and inhibiting JAKs or competing with STATs for phosphotyrosine-binding sites on cytokine receptors. Evidence is emerging for the involvement of suppressors of cytokine signaling proteins in human disease, which raises the possibility that therapeutic strategies based on the manipulation of suppressors of cytokine signaling activity might be of clinical benefit.

One particular subset of cytokines is termed *chemokines* for their ability to influence the movement of leukocytes and to regulate their migration to and from secondary lymphoid organs, blood, and tissues. Chemokines, or chemotactic cytokine chemokines, are a unique set of cytokines that are structurally homologous, 8- to 10-kDa polypeptides that have a varying number of cysteine residues in conserved locations that are key to forming their 3D shape. The two major families are CC chemokines (also called β), in which the two defining cysteine residues are adjacent, and the CXC (or α) chemokine family, in which these residues are separated by one amino acid. There are numerous CC (1–28) and CXC (1–16) chemokines with various targets and functions. The CC and CXC chemokines are produced not only by leukocytes but also by several other cell types, such as endothelial and epithelial cells as well as fibroblasts. In many circumstances, these cell types are stimulated to produce and to release the chemokines after recognition of microbes or other tissue injury signals detected by the various cellular receptors of the innate immune system discussed earlier. Although there are exceptions, recruitment of neutrophils is mainly mediated by CXC chemokines, monocyte recruitment is more dependent on CC chemokines, and lymphocyte homing is modulated by both CXC and CC chemokines. Chemokine receptors are G protein–coupled receptors containing seven transmembrane domains. These receptors initiate intracellular responses that stimulate cytoskeletal changes and polymerization of actin and myosin filaments, resulting in increased cell motility. These signals may also change the conformation of cell surface integrins, increasing their affinity for their ligands, thus affecting migration, rolling, and diapedesis. Thus, chemokines work in concert with adhesion molecules, such as integrins and selectins, and their ligands to regulate the migration of leukocytes into tissues. Distinct combinations of chemokine receptors are expressed on various types of leukocytes, resulting in the differential patterns of migrations of those leukocytes. In addition to cytokines, a host of other soluble, small-molecule mediators are released during an immune response or with other types of inflammation. These function to increase blood flow to the area and to improve the exposure of the area to lymphocytes and the innate immune system.

B Cells and Antibody Production

The primary lymphoid organ responsible for B-cell differentiation is the bone marrow. Similar to all other cells in the immune system, B cells are derived from pluripotent bone marrow stem cells. IL-7, produced by bone marrow stromal cells, is a growth factor for pre-B cells. IL-4, IL-5, and IL-6 are cytokines that stimulate the maturation and proliferation of mature primed B cells. The principal function of B cells is to produce antibodies against foreign antigens (i.e., the humoral immune response) as well as to be involved in antigen presentation. B-cell development occurs through several stages, each stage representing a change in the genomic content at the antibody loci. During the differentiation process, a similar process of V(D)J recombination as described for TCR diversity occurs, resulting in a nearly unlimited array of antibody specificities (see Fig. 49.10).

Similar to the T cell and its receptor, each B cell has a unique membrane-bound receptor through which it recognizes specific antigen. In the case of the B cell, this Ig molecule may also be produced in a secreted form that can interact with the extracellular environment far from its cellular origin. Each mature B cell produces antibody of a single specificity.

Each antibody is composed of two heavy chains and two light chains. Five different heavy chain loci (μ, γ, α, ε, and δ) are found on chromosome 14, and two light chain loci (κ and λ) are located on chromosome 2. Ig has a basic structure of four chains, two of which are identical heavy chains and two of which are identical light chains (Fig. 49.15). Both heavy and light chains have a constant region as well as a variable antigen-binding region. The antigen-binding site is composed of both the heavy and light chain variable regions. The ability of antibody to neutralize microbes is entirely a function of this antigen-binding region.

In humans, there are nine different Ig subclasses or isotypes: IgM, IgD, IgG1, IgG2, IgG3, IgG4, IgA1, IgA2, and IgE. Heavy chain use defines the subtype of any given antibody. Whereas the variable regions are involved in antigen binding, the constant regions have functionality as well. The fragment crystallizable region, or Fc region, is in the tail portion composed of the two heavy chain constant regions. It interacts with Fc receptors on phagocytic cells of the innate immune system to facilitate opsonization and subsequent destruction of the antigen to which the antibody is bound as well as facilitating antigenic peptide

processing. The Fc portion of IgM and some classes of IgG also serve to activate complement. Distinct immune effector functions are assigned to each isotype. IgM and IgG antibodies provide a pivotal role in the endogenous or intravascular immune response. IgA is primarily responsible for mucosal immunity and is largely confined to the gastrointestinal and respiratory tracts. Resting B cells that have not yet been exposed to antigen express IgD and IgM on their cell surface. After interaction with antigen, the first isotype produced is IgM, which is efficient at binding complement to facilitate phagocytosis or cell lysis. Further activation and differentiation of the B cell occur after interactions with CD4+ Tfh cells. B cells undergo isotype switching, which results in a decrease in IgM titer with a concomitant rise in IgG titer. Unlike the TCR, the Ig loci undergo continued alteration after B-cell stimulation to improve the affinity and functionality of the secreted antibody. A primed B cell may undergo further mutation within the variable regions that leads to increased affinity of antibody, termed *somatic hypermutation.* Such B cells are retained to provide the ability to generate a more vigorous response if the antigen happens to be re-encountered (Fig. 49.16).

B-cell activation occurs when antigen is bound by two surface antibodies (or a multimeric form of antibody) and the antibodies are brought together on the cell surface in a process known as *cross-linking.* This event stimulates B-cell activation, proliferation, and differentiation into various B-cell subsets and antibody-secreting plasma cells. As with T cells, the threshold for B-cell activation is high. This can be lowered 100-fold by costimulatory signals received by the transmembrane complex CD19-CD21. B cells can also internalize antigens bound to surface antibodies and process them for presentation to T cells, thus participating in antigen presentation. As discussed earlier, B cells may provide and receive certain costimulatory signals. For example, B cells express CD40, and when bound by CD154 expressed on activated T cells, the result is upregulation of B7 molecules on the B cell and delivery of important costimulatory signals to T cells as well.

Plasma cells reside in the bone marrow and are distinguished histologically by their hypertrophied Golgi apparatus resulting from their high degree of protein synthesis. They secrete large amounts of monoclonal (single specificity) antibody and exhibit phenotypic and functional characteristics distinct from other B cells that are the focus of therapeutic strategies to target plasma cells either for oncologic purposes or for the control of alloantibodies in transplantation.

In addition to being secreted in an adaptive manner after exposure to antigen, antibody can exist as part of the innate or natural immune repertoire in the circulation for initial response to common pathogens. Antigen exposure generally leads to B-cell affinity maturation and isotype switching and produces high-affinity IgG antibodies. Naturally occurring antibodies, however, are generally IgM antibodies with low affinity and are generally thought to bind to a broad array of carbohydrate epitopes found on many common bacterial pathogens. Natural antibody is responsible for ABO blood group antigen responses and discordant xenograft rejection (see "Xenotransplantation").

This portion of the chapter has reviewed the various components of the immune system and their function in the context of conventional infectious immune challenges. The next sections address the unique nature of the immune response to transplanted tissue and organs.

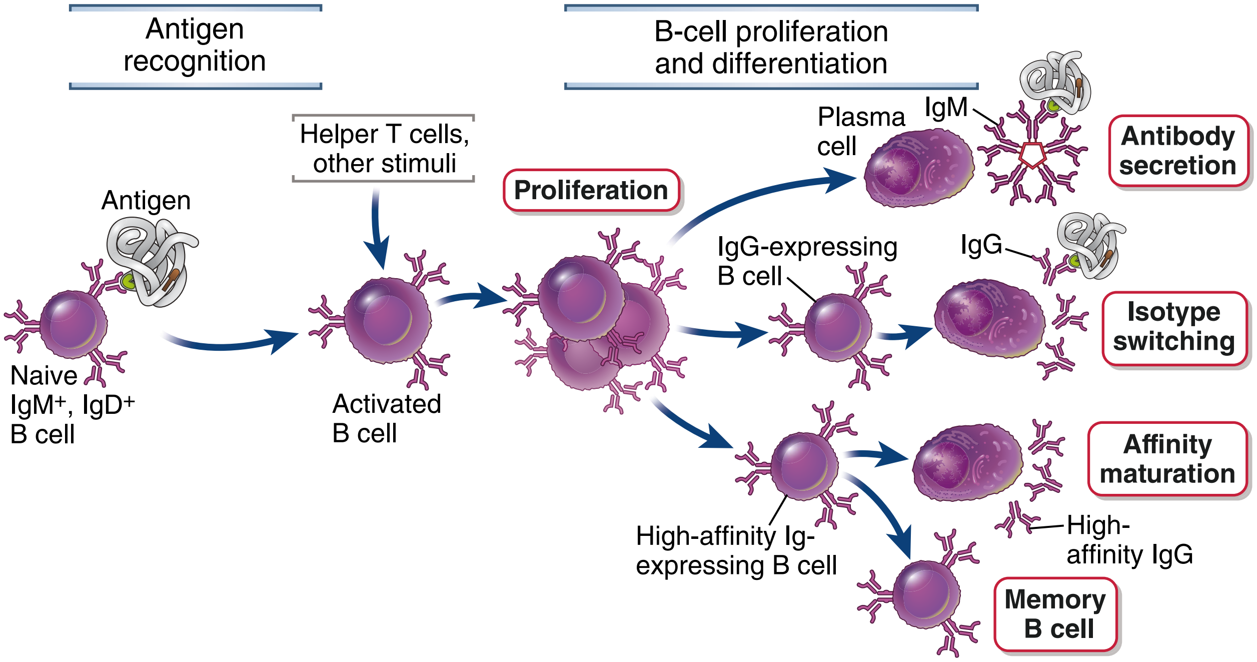

FIGURE 49.16 B-cell differentiation. Naïve B cells recognize their specific antigen as it binds to surface-bound antibody. Under the influence of helper T cells, costimulatory signals, and other stimuli, B cells become activated and clonally expand, producing many B cells of the same specificity. They also differentiate into antibody-secreting cells, plasma cells. Some of the activated B cells undergo heavy chain class switching and affinity maturation. Ultimately, a small subset become long-lived memory cells, primed for future responses. *Ig,* Immunoglobulin; *IgD,* immunoglobulin D; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M. TRANSPLANT IMMUNITY

The study of modern transplant immunology is traditionally attributed to the experiments of Sir Peter Medawar, fueled by attempts to use skin transplantation as a treatment for burned aviators during World War II. While monitoring the victims with autologous (syngeneic) and homologous (allogeneic) skin grafts, he noted that not only did all allogeneic grafts universally fail promptly but also secondary grafts from the same donor were rejected even more vigorously, suggesting immune involvement. He pursued this hypothesis with extensive experiments in rabbits, wherein he confirmed his previous observation and noted the presence of a heavy lymphocyte infiltrate in the rejecting graft. It was N.A. Mitchison, working in the early 1950s, who definitively identified a role for lymphocytes in the rejection of foreign tissue. Subsequent studies in tumor immunology as well as work by Snell using strains of genetically identical mice identified the genetic basis for graft rejection as the MHC, known in humans as HLA and in mice as the H-2 locus. These series of experiments during a short period of several years demonstrated that rejection of transplanted tissue was an immunologic process, implicated lymphocytes as the principal effector cells, and identified the MHC as the primary source of antigen in the rejection response. These pivotal studies laid the groundwork for the transition of transplantation from the experimental to the clinical realm.

Whereas the technical skill for the transplantation of skin and other organs had been available for some time, the vigorous rejection of allografts had prevented its widespread use for many years. It was not until 1954, after Medawar's critical studies had been published, that the first successful organ transplantation was performed. Despite Medawar's claim that the "biologic force" responsible for rejection would "forever inhibit transplantation from one individual to another," Joseph Murray, a surgeon-scientist, persevered in his pursuit of making clinical transplantation a reality. At the time, there was evidence to suggest that the overall immunologic barrier was lacking between identical twins, and coincidentally, Murray was busily perfecting a surgical technique for kidney transplantation in dogs. In 1954, the opportunity presented itself to test the hypothesis. Richard Herrick, who had end-stage renal disease, was the first candidate, and his identical sibling, Ronald, was willing to donate a kidney for transplantation to his brother. Murray confirmed the lack of immunologic reactivity between the two brothers by first placing skin grafts from each twin onto the other. Once he confirmed the lack of a response, he used the technique that he had perfected in the canine model, performing the first successful kidney transplant between identical twins in December 1954.[2] The operation proceeded without complication, and the kidney functioned well without the need for immunosuppression. Despite this landmark advance in transplantation, the majority of individuals in need of a transplant did not have an identical twin to donate an organ. Thereafter, the focus of the field was appropriately directed toward the development of methods to control the rejection response.

During the 1950s and 1960s, several discoveries were made that were of the utmost importance for future successes in transplantation. After Gorer and Snell's description of the murine MHC system, Jean Dausset described the equivalent in humans using antibodies developed against HLA. This led to the first serologically based typing system for human transplant antigens. Snell and Dausset shared the Nobel Prize in 1980 for their observations.

In the late 1960s, Paul Terasaki reported on the significance of preformed antibody directed against donor MHC molecules and its impact on kidney graft survival.[20] He developed the microlymphocyte cytotoxicity test, allowing pretransplantation detection of recipient-derived antidonor antibody. This formed the basis for the physical crossmatch assay that is used today to screen potential donor-recipient pairings. These techniques, along with the development of new immunosuppressive compounds, including 6-mercaptopurine and azathioprine, led to the first successful kidney transplantation between relatives who were not identical twins and also to the first successful transplant using a kidney from a deceased donor.

Although early attempts at immunosuppression permitted extended allograft survival in selected patients, both the reproducibility and durability of results were far from adequate. In the 1970s, investigators sought novel treatments to improve the success rate for transplantation; these modalities included thoracic duct drainage and the use of antilymphocyte serum. Despite these efforts, the results for kidney transplantation remained poor, with the best centers achieving 1-year survival rates of 70% for living related kidney grafts and 50% for deceased donor kidney transplants. Then a chance discovery of a promising agent from a fungal isolate dramatically changed the outlook for kidney and other types of transplantation. Jean-François Borel identified an active metabolite, cyclosporine A (CsA), that showed selective in vitro inhibition of lymphocyte cultures but no significant myelotoxic effects. Promising results in dogs eventually led to clinical trials in humans, and the modern era of transplantation had begun.

The introduction of CsA ushered in the most dramatic improvement in the field of transplantation (Fig. 49.17). Liver and heart transplant survival rates doubled, and the improved immunosuppression encouraged transplant teams around the world to begin broader investigational use, transplanting lung, small bowel, and pancreas. Now, with the use of CsA and newer agents such as tacrolimus, 1-year graft survival has exceeded 90% for virtually all organs

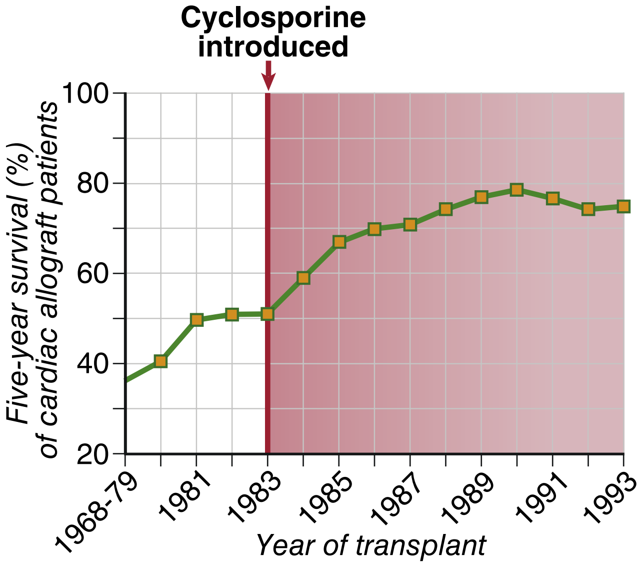

FIGURE 49.17 Influence of cyclosporine on transplant survival. Five-year survival rates for cardiac transplant recipients significantly increased with the introduction of cyclosporine in 1983. (Adapted from Abbas AK, Lichtman AH, Pillai S. *Cellular and Molecular Immunology*. 10th ed. Philadelphia: Saunders Elsevier; 2021.)

except the small intestine. Despite the discovery and clinical introduction of ever increasingly potent immunosuppressants, the field of transplantation has many areas in need of improvement. Drug-related side effects and the intractable problem of chronic rejection still plague practitioners. One area of focus of current research is the development of a clinically applicable strategy to promote "transplantation tolerance," thereby eliminating the pitfalls and shortcomings of current immunosuppressive therapy.

Rejection

There are three classic histopathologic definitions of allograft rejection that are based on not only the predominant mediator but also the timing of the process.

1. Hyperacute rejection occurs within minutes to days after transplantation and is primarily mediated by preformed donor-specific antibody (DSA) in the recipient.
2. Acute rejection is a process mediated most commonly by T cells but is often accompanied by an acquired antibody response and generally occurs within the first few weeks to months of transplantation (but can occur at any time).
3. Chronic rejection is a common contributing cause of long-term allograft loss and is an indolent fibrotic process that occurs over months to years. It is thought to be secondary to chronic immunologic injury from both T- and B-cell–mediated processes (including antidonor antibodies) but is difficult to completely separate from nonimmune mechanisms of chronic organ damage (e.g., drug toxicity and cardiovascular comorbid diseases).

Hyperacute Rejection

Although essentially untreatable, hyperacute rejection is nearly universally avoidable with the proper use of the lymphocytotoxic crossmatch or other means of detecting antidonor antibodies before transplantation. This form of rejection occurs when preformed antibodies against the donor, commonly referred to as *donor-specific antibodies,* are present in the recipient's system before transplantation (Fig. 49.18). These antibodies may be the result of "natural processes," such as the formation of antibody to blood group antigens, or the product of prior exposure to antigens with similar enough specificities as those expressed by the donor that cross-reactivity can occur. In the latter, sensitization is usually the result of prior transplantation, transfusion, or pregnancy but may also result from prior environmental antigen exposure. As expected, hyperacute rejection can occur within the first minutes to hours after graft reperfusion. Antibodies bind to the donor tissue or endothelium and initiate complement-mediated lysis and endothelial cell activation, resulting in a procoagulant state and immediate graft thrombosis. On histologic evaluation, there may be platelet and fibrin thrombi, early neutrophil infiltration, and positive staining for the complement product C4d on the endothelial lining of small blood vessels. Thankfully, this type of rejection is avoidable with pretransplantation testing by current crossmatch assays.

A physical crossmatch test is often employed to minimize the risk of hyperacute rejection. Similar to the lymphocytotoxicity assay described previously that is used for MHC class I typing, the physical crossmatch is performed by mixing cells from the donor

with serum from the recipient and the addition of complement if needed. Lysis of the donor cells indicates that antibodies directed against the donor are present in the recipient's serum; this is called a *positive crossmatch.* Thus, a negative crossmatch assay coupled with proper ABO matching will effectively prevent hyperacute rejection in 99.5% of transplants. Newer crossmatch techniques have become increasingly sophisticated, including those directed at both class I and class II antibodies, flow cytometric techniques, and bead-based screening assays to exclude non-HLA antibodies. As a given patient's sensitivity status may change over time, a more common technique for screening a patient's sensitization status is to screen a potential recipient's serum against a panel of random donor cells representing the anticipated regional donor pool. Known as the *panel reactive antibody (PRA) assay,* the results are expressed as a percentage of the panel within the randomly selected cell set that lyses when recipient serum is added. Thus, a nonsensitized patient would be given a score of 0%, and a highly sensitized patient might have a PRA score up to 100%. These screens can now be performed without the need for cells by using polystyrene beads coated with HLA antigens (Fig. 49.19). In this situation, the laboratory detects all anti-HLA antibodies and determines a calculated PRA (cPRA) score on the basis of the expected frequency of the HLA types in the donor pool. In the event a compatible donor is not available for a highly sensitized recipient, clinical protocols exist to attempt desensitization that uses plasmapheresis or intravenous immunoglobulin (IVIG) to reduce circulating antibody and prevent hyperacute rejection.[21] However, the need for desensitization is decreasing with advancements in deceased donor allocation algorithms and living donor paired donor exchange programs aimed at avoiding crossmatch-positive donor-recipient pairs.

Acute Rejection

Of the three types of rejection, only acute rejection can be successfully reversed once it is established. T cells constitute the core element responsible for acute rejection, often termed *T-cell–mediated rejection*. There is also a form of acute rejection that is particularly aggressive and involves vascular invasion by T cells known as *acute vascular rejection*. Finally, a more recently recognized form of acute rejection mediated by the humoral immune system, known as *antibody-mediated rejection (AMR),* is discussed briefly later. With the advent of increasingly effective immunosuppression, allograft loss from acute cellular rejection has become increasingly rare. Acute rejection can occur at any time after the first few postoperative days—the time needed to mount an acquired immune response; it most commonly occurs within the first 6 months after transplantation. Without adequate immunosuppression, the cellular response will progress during the course of days to a few weeks, ultimately destroying the allograft. As described earlier, there are two main pathways through which rejection can proceed: the direct and indirect alloresponses (Fig. 49.20). In either case, alloreactive T cells encounter their specific antigen (either processed donor MHC peptides indirectly presented on self MHC or directly recognized donor MHC), undergo activation, and promote similar rejection responses. of T cells specific for either direct allorecognition or indirect allorecognition differs.[12] Indirect allorecognition is theoretically similar to that of any given pathogen. Donor MHC protein is processed into peptides and presented on self MHC. The number of T cells specific for this antigen is approximately 1 in 200,000 to 1 in 500,000. Direct allorecognition, however, has a much higher precursor frequency. These T cells recognize donor MHC directly without processing (Fig. 49.21). Given that T cells are selected to recognize self MHC molecules and that there are similarities between donor and recipient MHC, it is no surprise that a substantial number of T cells are alloreactive. Some estimates suggest that somewhere between 1% and 10% of all T cells are directly alloreactive.[12] This high precursor frequency likely overwhelms many of the regulatory processes in place to control the much lower cell frequencies involved in physiologic immune responses. These alloreactive T cells, once activated, move to attack the graft. Subsequently, there is massive infiltration of T cells and monocytes into the allograft, resulting in organ injury through direct cytolysis and a general inflammatory milieu that leads to generalized parenchymal dysfunction and endothelial injury resulting in thrombosis (Fig. 49.22).

The bulk of current immunosuppressive agents are directed toward the T cells themselves or interruption of pathways essential to their activation or effector functions. In an effort to prevent acute cellular rejection, induction therapy is generally used during the initial stages after transplantation. These agents are discussed in the subsequent section but are most often antibody therapies that serve to globally deplete or inactivate T cells during the immediate postoperative period of engraftment when ischemia-reperfusion injury is most likely to promote immune recognition. Immunosuppressive regimens are frequently designed to favor more intensive initial immunosuppression in the immediate postoperative period and are then tapered to lower, less toxic levels over time.

T-cell–specific treatments lead to the prevention of acute rejection in approximately 70% of transplants, and when it does occur, it can be reversed in most cases. Similar to hyperacute rejection resulting from preformed antibody responses, T-cell presensitization

will result in an accelerated form of cellular rejection mediated by memory T cells. It generally occurs within the first 2 or 3 days after transplantation and can be accompanied by a significant humoral response.

The humoral equivalent to acute cellular rejection is AMR. This occurs when offending antibodies specific for alloantigen exist in the circulation at levels undetectable by crossmatch assays or, alternatively, B-cell clones capable of producing DSA are activated and stimulated to produce de novo alloantibodies. These antibodies are thought to bind HLA antigens within the graft, recruit innate and adaptive immune mechanisms, and acutely injure the transplanted organ (Fig. 49.23). The former scenario is often seen in patients with a high PRA score that has decreased over time. Transplantation presumably leads to restimulation of memory B cells responsible for the donor-specific antibodies. The result is initial graft function, followed by rapid deterioration within the first few postoperative days. Implementation of a more aggressive immunosuppressive regimen, including higher doses of steroids combined with nonspecific antibody reduction by plasmapheresis or IVIG (nonspecific Ig), is occasionally successful in acutely reversing AMR.

Prompt recognition of acute rejection is essential to ensure optimal graft survival. Untreated rejection leads to expansion of the immune response to involve multiple pathways, some of which are less sensitive to T-cell–specific therapies. In addition, damage to the allograft, particularly for kidney, pancreas, and heart, is generally accompanied by a permanent loss of function that is proportional to the magnitude of involvement. Most acute rejection episodes are initially asymptomatic until the secondary effects of organ dysfunction occur. By this point, the rejection process has proceeded to a point that it is often more difficult to reverse. Accordingly, monitoring for acute rejection is usually intense initially, particularly during the first year after transplantation. In general, any unexplained graft dysfunction should prompt biopsy and evaluation for the lymphocytic infiltration, antibody deposition, and parenchymal necrosis characteristic of acute rejection.

Novel Diagnostic Strategies for Acute Rejection

Since the dawn of transplantation, allograft biopsy has been the gold standard for the diagnosis of acute cellular rejection. Recently, several promising techniques have emerged to attempt diagnosis of acute rejection without biopsy, obviating the complications that occasionally arise with invasive interventions such as needle biopsy. One of the most promising of these new techniques for assessing the presence of acute rejection is the characterization of donor-derived cell free DNA (dd-cfDNA) in the serum. During processes of graft injury like acute rejection, dd-cfDNA is liberated into the circulation as donor allograft cells die or become inflamed, and sensitive PCR techniques can amplify and quantify this transplant-specific cfDNA. For example, one specific test analyzes single nucleotide polymorphisms (SNPs) across all 22 somatic chromosomes to optimize dd-cfDNA detection. The dd-cfDNA assays have found numerous clinical applications, such as capturing incipient rejection responses while switching or adjusting immunosuppression regimens, monitoring rejection treatment response, identifying rejection in patients with delayed or slow graft function, and substituting for invasive tissue biopsies in high-risk recipients (such as anticoagulated patients, for whom biopsy would be at increased risk of complication).[22] The Circulating Donor-Derived Cell-Free DNA in blood for diagnosing Acute Rejections

in Kidney Transplant Recipients (DART) study found that dd-cfDNA significantly outperformed serum creatinine in detecting active rejection in renal allograft recipients, especially for discriminating AMR. Similarly, the Resolution by AlloSure Differentiates Ambiguous Rejection (RADAR) study found that a dd-cfDNA level >0.5% can help risk-stratify patients with grade 1A or borderline rejection with respect to poor clinical outcomes such as estimated glomerular filtration rate (eGFR) decline, formation of de novo DSA, or future recurrent rejection episodes. The use of dd-cfDNA has also been validated for heart and lung transplant recipients.

Another US Food and Drug Administration (FDA)–approved assay measures adenosine triphosphate production by peripheral blood CD4+ T cells as a marker of global immune competence. This assay enables clinicians to determine which transplant recipients may be functionally over-immunosuppressed (and thus at increased risk of opportunistic infection) and which patients may be functionally under-immunosuppressed (and thus at increased risk of allograft rejection). Finally, some researchers are also exploring other noninvasive diagnostic tests for acute allograft rejection, such as use of urinary biomarkers in kidney transplant recipients. A variety of different urinary biomarkers such as IL-18, CXCL9, and CXCL10 have been validated for the diagnosis of renal allograft rejection. In total, although these assays promise to unlock future standards of noninvasive diagnostic testing, limitations on their sensitivity and specificity do not currently allow them to substitute for gold standard allograft biopsy. In particular, these assays may be too sensitive and not specific enough, having demonstrated difficulty distinguishing allograft rejection from other causes of allograft dysfunction such as urinary tract infection or BK nephropathy.

Chronic Rejection

Whereas the mechanisms of acute and hyperacute rejection are now well-described, chronic rejection remains less understood. True chronic rejection is an immune-based process derived from repeated or indolent T-cell–mediated rejection or AMR, but the clinical phenotype of chronic graft fibrosis and deterioration is often secondary to a combination of both immune and nonimmune effects. Appropriately, the term *chronic rejection* has been substituted with more descriptive terms: interstitial fibrosis and tubular atrophy (previously chronic allograft nephropathy) for kidneys, chronic coronary vasculopathy for hearts, vanishing bile duct syndrome for livers, and bronchiolitis obliterans for lungs.[23] The process is insidious, usually occurring during a period of years, but it can be accelerated and occur within the first year. Regardless of the organ involved, it is characterized by parenchymal replacement by fibrous tissue with a relatively sparse lymphocytic infiltrate but may contain macrophages or dendritic cells. Organs with epithelium show a disappearance of the epithelial cells as well as endothelial destruction. The events that ultimately trigger this response are certainly related to the transplantation, including but not limited to the response to alloantigen as well as myriad nonimmune factors such as ischemia-reperfusion injury, cytomegalovirus (CMV) infection, CNI toxicity, and posttransplant metabolic disease. These events set the stage for expression of various soluble factors, including TGF-β, leading to a remodeling of the parenchyma and ensuing fibrous replacement (Fig. 49.24). Chronic inflammatory insults can also evoke a process of epithelial-to-mesenchymal dedifferentiation, leading to epithelial cells that regress into fibrocytes. Although to date these processes remain essentially untreatable once identified, several factors have been identified that predispose toward the development of chronic rejection. The most important of these is prior acute rejection episodes. Another important factor is the presence of DSA, which often portends premature allograft loss. Thus, the more effectively immune control is exerted to limit acute rejection episodes and the development of donor-specific antibodies in the early stages after transplantation, the less likely chronic rejection related to immune injury is to occur.

IMMUNOSUPPRESSION

Current immunosuppressive therapies in transplantation achieve excellent results, especially in terms of relatively short-term patient and allograft survival rates. Despite tremendous progress during the past 60 years, all agents designed to prevent rejection remain nonspecific to the alloimmune response. Given the redundancy of the immune system, recipients almost always need multiple agents to adequately control the normal immune response. In addition, none of these therapies specifically inhibit the response to the allograft; instead, most immunosuppressants target the immune response globally. In other words, all drugs that prevent rejection do so at the cost of suppressing the normal host response to bacterial and viral pathogens as well as tumor surveillance. Whereas some of the newer therapies are more precise in their mechanisms and selective for immune cells, many target not only the mediators of the immune response but also any cells undergoing maturation or division. Consequently, many nonimmune side effects are associated with immunosuppressive therapy that can directly or indirectly contribute to graft dysfunction and loss. In addition, the societal costs are not trivial, considering that transplant recipients may take dozens of pills a day at an annual cost of $10,000 to $15,000.

The most critical time for immune protection is the first few days to months after transplantation. The graft is fresh, and there is a heightened state of inflammation secondary to inevitable graft injury from ischemia-reperfusion as well as the physical transfer of the organ itself. In addition, this is the time of initial antigen exposure, which plays a large role in determining the long-term status of immune responsiveness. For this reason, immunosuppression is extremely intense in the early postoperative period and normally tapered thereafter. This initial conditioning of the recipient's immune system is known as *induction immunosuppression*. It most commonly involves depletion, or at least aggressive reduction, of T cells and consequently is tolerated only for a short time without lethal consequences. After this initial period, the agents used to prevent acute rejection for the remainder of the life of the transplanted organ are called *maintenance immunosuppressants*. These medications still carry with them a host of immune and nonimmune side effects that may also ultimately contribute to long-term graft failure. Immunosuppressants used to reverse an acute rejection episode are called *rescue agents*. They are generally the same as those agents used for induction therapy. The mechanisms of the various immunosuppressants are described here and detailed in Table 49.3.

Induction Therapy

Most of the current induction regimens involve the use of some depleting antilymphocyte antibody preparation. Their mechanism of action is probably not fully understood but involves some combination of either selective or nonselective depletion and inactivation. They cause profound immunosuppression,

Philadelphia: Saunders Elsevier; 2021.)

placing the recipient at increased risk for opportunistic infections or malignancies such as lymphoma, and are consequently generally limited to short-term use on the order of days to weeks.

Antithymocyte Globulin

Antithymocyte globulin preparations are produced by immunizing another species with an inoculum of human thymocytes consisting primarily of lymphocytes, followed by collection of the sera and purification of the gamma globulin fraction. The result is a polyclonal antibody preparation that contains antibodies directed against a multitude of antigens on lymphocytes. The two most commonly used preparations are rabbit antithymocyte globulin (RATG) and horse antithymocyte globulin (ATGAM). RATG seems to be more effective than ATGAM at reducing the incidence of acute rejection episodes and consequently is the preferred preparation at most US transplantation centers.[24] The polyclonal preparation consists of hundreds of polyclonal antibodies that coat dozens of epitopes over the surface of the T cell. The result is T-cell clearance through complement-mediated lysis and opsonization. In addition to simple depletion mechanisms, the antisera also interfere with effective TCR signaling and can promote inappropriate cross-linking of key cell surface molecules, including adhesion and costimulatory receptors, resulting in unresponsiveness or anergy.

These preparations are used as induction agents as well as rescue treatment for acute rejection episodes. Most commonly, RATG is used as part of a multidrug induction protocol that includes a CNI, an antiproliferative agent such as mycophenolate mofetil (MMF), and prednisone. One strategy in renal transplantation is the sequential use of RATG followed by a CNI to avoid the nephrotoxic effects of the CNI in the early posttransplantation period as well as to maximize the effects of RATG by depleting or inactivating the majority of T cells at the critical time of graft introduction. More recently, RATG has been used as a key component of newer steroid-minimization or CNI-free regimens.[25,26]

Many of the side effects associated with RATG administration are related to its polyclonal composition. Surprisingly, only a small fraction of the known specificities are actually directed at defined T-cell epitopes. One major side effect is profound thrombocytopenia secondary to platelet-specific antibodies within the polyclonal preparation. In addition to T-cell depletion, leukopenia and anemia may also result. Overimmunosuppression is also a concern; given that these preparations are extremely effective at T-cell depletion, there is an increase in viral reactivation and primary viral infections, including CMV, Epstein-Barr virus (EBV), herpes simplex virus, and varicella-zoster virus. The effect on EBV-specific T cells also predisposes treated patients to a higher incidence of EBV-associated lymphoid malignant neoplasms. Overall, however,

TABLE 49.3 Summary of Immunosuppressive Drugs

DRUG	DESCRIPTION	MECHANISM	NONIMMUNE TOXICITY AND COMMENTS
Prednisone	Corticosteroid	Binds nuclear receptor and enhances transcription of IκB, which inhibits NF-κB and T-cell activation	Diabetes, weight gain, psychological disturbances, osteoporosis, ulcers, wound healing, adrenal suppression
Cyclosporine	11–Amino acid cyclic peptide from *Tolypocladium inflatum*	Binds to cyclophilin; complex inhibits calcineurin phosphatase and T-cell activation	Nephrotoxicity, hemolytic uremic syndrome, hypertension, neurotoxicity, gingival hyperplasia, skin changes, hirsutism, posttransplantation diabetes, hyperlipidemia
Tacrolimus (Prograf)	Macrolide antibiotic from *Streptomyces tsukubaensis*	Binds to FK-BP12; complex inhibits calcineurin phosphatase and T-cell activation	Effects similar to CsA but with lower incidence of hypertension, hyperlipidemia, skin changes, hirsutism, and gingival hyperplasia but higher incidence of posttransplantation diabetes and neurotoxicity
Sirolimus (Rapamycin)	Triene macrolide antibiotic from *Streptomyces hygroscopicus* from Easter Island (Rapa Nui)	Binds to FK-BP12; complex inhibits target of rapamycin and IL-2–dependent T-cell proliferation	Hyperlipidemia, increased toxicity of calcineurin inhibitors, thrombocytopenia, delayed wound healing, delayed graft function, mouth ulcers, pneumonitis, interstitial lung disease
Everolimus (Zortress)	Derivative of sirolimus, similar mechanism and toxicities		
Mycophenolate mofetil (CellCept)	Mycophenolic acid from *Penicillium stoloniferum*	Inhibits synthesis of guanosine monophosphate nucleotides; blocks purine synthesis, preventing proliferation of T and B cells	Gastrointestinal symptoms (mainly diarrhea), neutropenia, mild anemia
Azathioprine (Imuran)	Prodrug that undergoes hepatic metabolism to form 6-mercaptopurine	Converts 6-mercaptopurine to 6-thioinosine-5′-monophosphate, which is converted to thioguanine nucleotides that interfere with DNA and purine synthesis	Leukopenia, bone marrow depression, liver toxicity (uncommon)
Antithymocyte globulin	Polyclonal IgG from rabbits or horses immunized with human thymocytes	Blocks T-cell membrane proteins (CD2, CD3, CD45), causing altered function, lysis, and prolonged T-cell depletion	Cytokine release syndrome, thrombocytopenia, leukopenia, serum sickness
OKT3 (muromonab-CD3)	Anti-CD3 murine monoclonal antibody	Binds CD3 associated with the TCR, leading to initial activation and cytokine release, followed by blockade of function, lysis, and T-cell depletion	Severe cytokine release syndrome, pulmonary edema, acute renal failure, central nervous system changes
Basiliximab	Anti-CD25 chimeric monoclonal antibody	Binds to high-affinity chain of IL-2R (CD25) on activated T cells, causing depletion and preventing IL-2–mediated activation	Hypersensitivity reaction, uncommon
Daclizumab	Anti-CD25 humanized monoclonal antibody	Similar to that of basiliximab	Hypersensitivity reaction, uncommon
Rituximab	Anti-CD20 chimeric monoclonal antibody	Binds to CD20 on B cells and causes depletion	Infusion and hypersensitivity reactions, uncommon
Alemtuzumab	Anti-CD52 humanized monoclonal antibody	Binds to CD52 expressed on most T and B cells, monocytes, macrophages, and NK cells, causing lysis and prolonged depletion	Mild cytokine release syndrome, neutropenia, anemia, autoimmune thrombocytopenia, thyroid disease
Belatacept (LEA29Y)	High-affinity homologue of CTLA-4–Ig	Binds to CD80/CD86 and prevents costimulation through CD28	In clinical trials, results show improved glomerular filtration rate and improved outcomes to CsA

the drug is well tolerated by most transplant recipients and is the most common form of induction treatment used in kidney transplantation. The most common symptoms are the result of transient cytokine release after antibody binding and cell lysis. Chills and fevers occur in up to 20% of patients, but this cytokine release syndrome is usually self-limited and treatable with antipyretics and antihistamines. In addition, this response is often tempered in patients receiving corticosteroids as part of the induction regimen.

Anti–IL-2 Receptor Antibodies

The cytokine IL-2 plays a critical role in T-cell activation and function. After antigen recognition and signal transduction through the TCR complex, expression of IL-2 and its receptor is markedly upregulated. The receptor consists of three chains: α (CD25), β (CD122), and the common cytokine receptor γ chain (CD132). These chains associate in a noncovalent manner to form the IL-2 receptor complex. The α chain, CD25, is a type I transmembrane protein that is responsible for the high-affinity binding of IL-2 on activated T cells and is critical for T-cell clonal expansion (Fig. 49.25). Given its importance in the cellular response, two nondepleting monoclonal antibodies (mAbs) specific for CD25 were developed and approved for use in transplantation: daclizumab and basiliximab.[27,28] The two antibodies differ in their composition in that daclizumab is humanized and

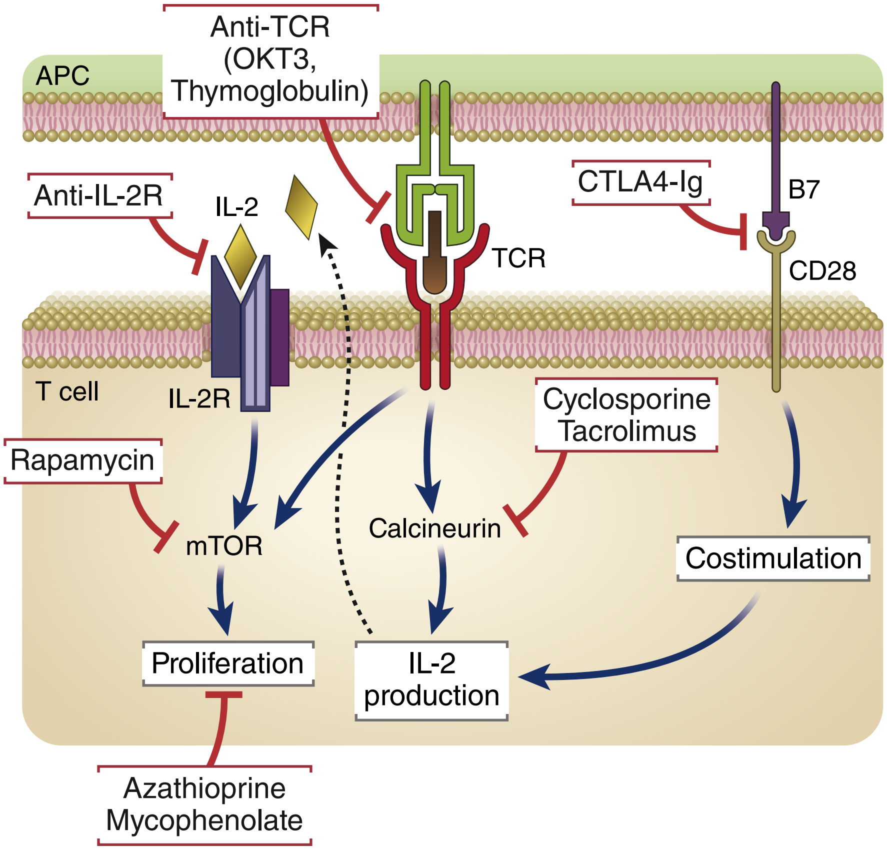

FIGURE 49.25 Molecular mechanisms of immunosuppression. Immunosuppressants may be small molecules, antibodies, or fusion proteins that block various pathways critical for T-cell activation. TCR activation is blocked by anti-TCR monoclonal and polyclonal antibodies such as OKT3 and thymoglobulin. Downstream signaling from TCR activation is blocked by calcineurin inhibitors such as cyclosporine and tacrolimus, which prevent the calcineurin-mediated dephosphorylation of NFAT necessary for the nuclear translocation of this critical transcription factor. Costimulation signals necessary for T-cell activation (such as CD28-B7 interaction) are interrupted by costimulatory blockade fusion proteins such as CTLA4-Ig and belatacept. IL-2 is a necessary cytokine permitting leukocyte proliferation, and this pathway is disrupted by both IL-2 receptor antagonists (such as basiliximab) and mTOR inhibitors such as rapamycin and everolimus. Antimetabolites such as azathioprine and mycophenolate interfere with nucleic acid metabolism and therefore disrupt cellular proliferation. Finally, prednisone (not shown) binds to cytoplasmic steroid receptors, which then translocate into the nucleus and function as transcription factors for multiple immunosuppressive genes. *CTLA,* Cytotoxic T lymphocyte–associated; *Ig,* immunoglobulin; *IKK,* IkB kinase; *IL,* interleukin; *mAb,* monoclonal antibody; *MMF,* mycophenolate mofetil; *MPA,* mycophenolic acid; *mTOR,* mammalian target of rapamycin; *NFAT,* nuclear factor of activated T cell; *TCR,* T-cell receptor. (Adapted from Abbas AK, Lichtman AH, Pillai S. *Cellular and Molecular Immunology.* 10th ed. Philadelphia: Saunders Elsevier; 2021.)

basiliximab is a mouse-human chimeric antibody. Both are directed against CD25 and function to block IL-2 binding. Because CD25 is preferentially expressed on recently activated T cells, the antibodies are semiselective in their effects, presumably affecting only T cells specific for the allograft that have been activated at the time of graft implantation. Once the T-cell response is well under way, effector T cells are much less dependent on CD25 expression, and these antibodies are much less effective. For this reason, both anti-CD25 antibodies are used during the induction phase only. Much like antithymocyte globulin, they have been shown to prevent or to reduce the frequency of acute rejection when they are used in combination with standard three-drug regimens.[27,28] However, in contradistinction to lymphocyte-depleting agents, daclizumab and basiliximab, although generally less potent, confer less risk of infection and malignancy posttransplant. More recently, they have been employed as part of regimens to reduce or eliminate CNIs or within steroid-minimization protocols. These anti–IL-2R antibodies are well tolerated clinically, as they do not precipitate the same side effects seen with antithymocyte globulin, such as the cytokine release syndrome. Unlike the murine antibody OKT3 (see “OKT3” next), both daclizumab and basiliximab are the products of genetic engineering, with some or all of the structural components of the mouse antibody having been replaced with human IgG, and thus, they are much less likely to invoke neutralizing antibody responses themselves. Daclizumab has since been discontinued as a result of diminished demand, leaving basiliximab as the sole anti–IL-2 receptor option.

OKT3

Muromonab-CD3 (OKT3), a murine mAb directed against the human CD3 ε chain (a component of the TCR signaling complex), was approved by the FDA for use in patients in 1986 and is now of purely historical interest. It was the first commercially available mAb preparation for use in organ transplantation with T-cell specificity devoid of the unintended bystander effects observed with polyclonal preparations. OKT3 was shown to be superior to conventional steroid therapy in reversing rejection and consequently improved allograft survival.[29] Because OKT3 is a mouse antibody, it can elicit an immune response to itself, and the recipient will generate antimurine antibodies directed against the structural regions of the antibody or the actual binding site, thereby limiting its therapeutic effect. In addition, the cytokine release syndrome associated with OKT3 administration can be vigorous, resulting in hypotension, pulmonary edema, and myocardial depression. Because of this vigorous response, its immunogenicity, and the availability of alternative therapeutic options, OKT3 has been withdrawn from production.

Alemtuzumab

Alemtuzumab was originally developed in the oncology field for the treatment of lymphoma. It is a humanized antibody against human CD52, a cell surface protein expressed on most mature lymphocytes and monocytes but not on their stem cell precursors. It has been used not only in patients with lymphoma but also in autoimmune processes, such as multiple sclerosis and rheumatoid arthritis. Administration of alemtuzumab is extremely effective at reducing the number of T cells both in the peripheral blood and in secondary lymphoid organs. In addition, it depletes, to a lesser extent, both B cells and monocytes. Unlike other strategies, this depletion may last for weeks to months after dosing. Investigational studies in transplantation employing alemtuzumab as an induction agent have allowed minimization of immunosuppression, particularly when it is combined with a CNI.[30,31] Its optimal use in transplantation remains to be established.

Maintenance Immunosuppression

After the immediate posttransplant period of induction, transplant recipients continue on long-term maintenance immunosuppression. Practice has evolved to maintain patients on standard multidrug regimens that have facilitated lower doses of individual agents to minimize toxicity and enhanced the quality of net immunosuppression through the use of various mechanisms of action. With outstanding short-term transplant outcomes, chronic use of maintenance agents and their attendant off-target toxicities have driven dose-reduction protocols over time and efforts to develop more selective and less toxic novel therapies.

Corticosteroids

Steroids, in particular glucocorticoids, remain one of the most commonly employed medications to prevent rejection. They are almost exclusively used in combination with other agents with which they seem to act synergistically to improve graft survival. They may also be used in higher doses as induction or rescue therapy for acute rejection episodes. Although steroids possess potent immunosuppressive properties, they can contribute significantly to the morbidity of transplantation by their effects on wound healing and propensity to cause diabetes, hypertension, and osteoporosis. With the advent of more effective and alternative immunosuppressive options over time, there has been an emphasis on developing steroid-minimization or steroid-sparing protocols to avoid these well-known side effects. Nonetheless, low-dose steroids remain a common component of current standard immunosuppressive regimens.

Although the Nobel Prize was awarded more than 50 years ago for work on the hormones of the adrenal cortex, the mechanism of the immunosuppressive effect of glucocorticoids was only recently better understood.[32] Similar to other steroid hormones, glucocorticoids bind to an intracellular receptor after passing into the cytoplasm through nonspecific mechanisms. The receptor-steroid complex then enters the nucleus, where it acts as a transcription factor. One of the most important genes upregulated is the gene encoding IκB. This protein binds to and inhibits the function of NF-κB, a key activator of proinflammatory cytokines and an important transcription factor involved in T-cell activation. Through this mechanism, steroids also act to diminish transcription of IL-1 and TNF-α by APCs as well as to prevent upregulation of MHC expression. Phospholipase A2, and consequently the entire arachidonic acid cascade, is also inhibited. They decrease the leukocyte response to various chemokines and chemotactins and by inhibiting vasodilators, such as histamine and prostacyclin, thus dampen the inflammatory response globally. This broad antiinflammatory response quickly mollifies the intragraft environment and thus substantially improves graft function long before the offending cells have actually left the graft. The most commonly used oral glucocorticoid formulation is prednisone; its intravenous equivalent is methylprednisolone.

Antiproliferative Agents

Azathioprine. The purine analogue azathioprine was first described in the 1960s and remained a mainstay of immunosuppression for the next 30 years.[33] It is still used today in organ transplantation and in the treatment of some autoimmune diseases, such as autoimmune hepatitis. Similar to other antiproliferative agents, it is a nucleotide analogue that targets cells undergoing rapid division; in the case of an immune response, its goal is to limit the clonal expansion of T and B cells. Azathioprine undergoes hepatic conversion to several active metabolites, including 6-mercaptopurine and 6-thioinosine monophosphate. These derivatives inhibit DNA synthesis by alkylating DNA precursors and interfering with DNA repair mechanisms. In addition, they inhibit the enzymatic conversion of thioinosine monophosphate to adenosine monophosphate and guanosine monophosphate, effectively depleting the cell of adenosine. The effects of azathioprine are relatively nonspecific, and like other antiproliferative agents, it acts on all rapidly dividing cells requiring nucleotide synthesis. Consequently, its predominant toxicities are seen in the bone marrow, gut mucosa, and liver. Azathioprine has been used as a maintenance agent in combination with other medications, such as a corticosteroid and CNI. Although it has largely been replaced by MMF as the first-line antiproliferative agent, azathioprine remains the agent of choice during pregnancy.

Mycophenolate mofetil. MMF is an immunosuppressive agent with a similar mechanism of action to azathioprine. It is derived from the fungus *Penicillium stoloniferum*. Once ingested, it is metabolized in the liver to the active moiety mycophenolic acid. The active compound inhibits inosine monophosphate dehydrogenase, the enzyme that controls the rate of synthesis of guanosine monophosphate in the de novo pathway of purine synthesis, a critical step in RNA and DNA synthesis. Importantly, however, is the presence of a "salvage pathway" for guanosine monophosphate production in most cells except lymphocytes (hypoxanthine-guanine phosphoribosyltransferase–catalyzed guanosine monophosphate production directly from guanosine). Thus, MMF exploits a critical difference between lymphocytes and other body tissues, resulting in relatively lymphocyte-specific immunosuppressive effects. MMF blocks the proliferative response of both T and B cells, inhibits antibody formation, and prevents the clonal expansion of cytotoxic T cells.

Numerous clinical trials have evaluated MMF. Specifically, MMF has been shown to decrease the rate of biopsy-proven rejection and the need for rescue therapy compared with azathioprine.[34] Accordingly, MMF has replaced azathioprine in most standard three-drug immunosuppressive regimens, although recent evidence suggests that its therapeutic difference is less pronounced when it is used with more modern immunosuppressive therapies. It has also been used in combination with either a CNI or sirolimus by many centers in steroid-sparing protocols. However, MMF is not effective enough to be used alone without either steroids or CNIs. The major clinical side effects include leukopenia and diarrhea. An advanced, enteric-coated formulation of mycophenolate sodium (Myfortic) that only releases in the high pH environment of the small intestine has been developed to mitigate some of the gastrointestinal side effects of MMF.

Calcineurin Inhibitors

Cyclosporine A. Jean-François Borel is credited with the discovery of CsA in 1972 while working as a microbiologist for Sandoz Laboratories (now Novartis). He apparently was vacationing in Norway and while there had collected soil samples for analysis in search of new antibiotics. Although the samples failed to show any significant antimicrobial activity, they did show potent immunosuppressive characteristics. Further studies demonstrated that the active component is a cyclic, nonribosomal peptide of 11 amino acids produced by the fungus *Tolypocladium inflatum.*[35] The mechanism of action of CsA is mediated primarily through its ability to bind the cytoplasmic protein cyclophilin. The CsA-cyclophilin complex binds to the calcineurin-calmodulin complex within the cytoplasm and blocks the phosphatase activity of calcineurin, preventing the dephosphorylation and resulting activation of NFAT, a critical transcription factor involved in T-cell activation, including upregulation of the IL-2 transcript (see Fig. 49.25). The result is blockade of IL-2 production. Thus, CsA is used as a maintenance agent, blocking the initiation of an immune response, but it is ineffective as a rescue agent once IL-2 has already been produced. In addition, CsA acts to increase transcription of TGF-β, a cytokine involved in the normal processes that limit the immune response by inhibiting T-cell activation, reducing regional blood flow, and stimulating tissue remodeling and wound repair. As discussed later, the toxicity and side effects of CsA may be in large part related to the effects of TGF-β.

CsA has poor water solubility and consequently must be given in a suspension or emulsion. This becomes a particular concern in liver transplantation because the oral absorption of CsA is dependent on bile flow; fortunately, this was addressed through the development of a microemulsion form that is less bile dependent. CsA is metabolized by the hepatic cytochrome P450 enzymes, and blood levels are therefore influenced by agents that affect the P450 system. P450 inhibitors, which include ketoconazole, erythromycin, calcium channel blockers, and grapefruit juice, result in higher CsA levels; inducers of P450, including rifampin, phenobarbital, and phenytoin, result in lower CsA levels.

The discovery of CsA and its subsequent development as an immunosuppressant contributed enormously to the advancement of organ transplantation (see Fig. 49.17). It was first approved for clinical use in 1983 and led to substantial improvement in the outcome of deceased donor renal transplantation and permitted the widespread practice of heart and liver transplantation.[36] Whereas its potent immunosuppressive activity was welcomed, its attendant toxicities were less than ideal. CsA induces the expression of TGF-β, and much of CsA's toxicity can be linked to increased TGF-β activity. One of the most important side effects of CsA is renal toxicity. CsA has a significant vasoconstrictor effect on proximal renal arterioles, resulting in a 30% decrease in renal blood flow. This action is most likely mediated through increased TGF-β levels that act to increase the transcription of endothelin, a potent vasoconstrictor, resulting in activation of the renin-angiotensin pathway and resultant hypertension. The remodeling effects of TGF-β also induce fibrin deposition, which is thought to play a role in the fibrosis typically seen during chronic allograft nephropathy. CsA frequently causes neurologic side effects consisting of tremors, paresthesias, headache, depression, confusion, somnolence, and, rarely, seizures. Hypertrichosis (increased hair growth) is another frequent side effect, predominantly occurring on the face, arms, and back in up to 50% of patients. Gingival hyperplasia may also occur. The use of CsA in combination with other immunosuppressive agents permitted lower doses of CsA to limit toxicity, but current mainstay immunosuppression now favors the CNI tacrolimus.

Tacrolimus. Tacrolimus was isolated from Japanese soil samples in 1984 as part of an effort to discover novel immunosuppressants. A macrolide produced by the fungus *Streptomyces tsukubaensis,* tacrolimus was found to possess potent immunosuppressive properties.[37] Similar to CsA, it blocks the effects of NFAT, prevents cytokine transcription, and arrests T-cell activation. The intracellular target is an immunophilin protein distinct from cyclophilin known as *FK-binding protein (FK-BP).* In vitro, tacrolimus was found to be 100 times more potent in blocking IL-2 and IFN-γ production than CsA and is clinically more effective at preventing acute rejection.[38] Tacrolimus, like CsA, also increases TGF-β transcription, leading to both the beneficial and toxic effects of this cytokine. The side effect profile for tacrolimus is similar to that of CsA with regard to renal toxicity, but the cosmetic side effects, such as abnormal hair growth and gingival hyperplasia, are substantially reduced. Neurotoxicity, including tremors and mental status changes, is more pronounced with tacrolimus, as is its diabetogenic effect. Tacrolimus has been shown to be extremely effective for solid organ transplantation and has become the cornerstone drug of choice for most centers.

Mammalian Target of Rapamycin Inhibitors

Sirolimus and everolimus. Sirolimus (rapamycin) was isolated from a soil sample taken from Easter Island, a Polynesian island in the southeastern Pacific Ocean also known as Rapa Nui, hence the name rapamycin. It is a macrolide derived from the bacterium *Streptomyces hygroscopicus* with potent immunosuppressive properties. Everolimus is a derivative of rapamycin that possesses similar properties. Both are similar in structure to tacrolimus and bind to the same intracellular target, FK-BP, but neither agent affects calcineurin activity and consequently does not inhibit expression of NFAT or IL-2. Instead, the sirolimus–FK-BP complex inhibits the mammalian target of rapamycin (mTOR), specifically the mTOR complex 1 (see Fig. 49.25). mTOR is also called FRAP (FK-BP–rapamycin-associated protein) or RAFT (rapamycin and FK-BP target). RAFT-1 is a critical kinase involved in the IL-2 receptor signaling pathway. The result is inhibition of p70 S6 kinase activity, an enzyme essential for ribosomal phosphorylation, and arrest of cell cycle progression. Other receptors are also affected, including those for IL-4, IL-6, and platelet-derived growth factor.

Both sirolimus and everolimus are potent inhibitors of rejection in experimental models. Sirolimus and tacrolimus can act synergistically to impair rejection, but the combination can result in intolerable clinical toxicity. For example, the TRANSFORM trial found that the combination of everolimus and low-dose CNI was noninferior to standard immunosuppression with CNI and MMF in renal transplant recipients, although the rate of study discontinuation for adverse medicine effects was twice as high in the everolimus group than in the MMF group.[39] More often, sirolimus is used as an alternative to CNIs in a multidrug regimen or combined with other agents, allowing a reduction in the dose and minimization of side effects, including CNI-related nephrotoxicity or steroid-specific side effects. In addition to immunosuppressive properties, mTOR inhibitors have been shown to have promising antitumor effects as well. For example, sirolimus has been shown to promote programmed cell death in B-cell lymphomas, and everolimus has demonstrated activity against EBV. Thus, both agents may play an important role in the prevention of posttransplantation lymphoproliferative disorder (PTLD). Sirolimus and everolimus have also been used in the development of drug-eluting coronary stents to limit the rate of in-stent restenosis because of their antiproliferative properties. There is an increased incidence of hypercholesterolemia and hypertriglyceridemia with both agents that often requires treatment with cholesterol-lowering agents or discontinuation of the drug. Oral ulcers, wound healing complications (in particular an increased incidence of lymphoceles), elevated levels of proteinuria, pneumonitis, and thrombocytopenia remain frequent problems and limit universal application.

Costimulation Blockade

Belatacept. Costimulation is a critical component of naïve T-cell activation and has been extensively studied as a potential target for immune modulation in organ transplantation. One of the most important costimulation pathways is the interaction between CD28 and CD80/CD86. Signaling through CD28 allows effective IL-2 production and promotes cell survival through upregulation of antiapoptotic molecules. CD152 (CTLA-4) is another cell surface molecule expressed on activated T cells that is more effective in binding CD80 and CD86 than CD28. Once activated, T cells begin to express CD152, which interacts with CD80 and CD86 with a higher affinity and effectively interferes with CD28 binding and may deliver inhibitory signals to the T cell as part of a downregulatory mechanism for the immune response. CTLA-4–Ig is a fusion protein consisting of the extracellular component of CTLA-4 and the heavy chain of human IgG1 that was developed to block CD28-CD80/CD86 interactions and consequently to impair costimulation and T-cell activation (see Fig. 49.25). CTLA-4–Ig (abatacept) is used clinically for several autoimmune indications, including rheumatoid arthritis and psoriasis. However, the observed immunosuppressive strength of abatacept in preclinical transplant studies was suboptimal; thus, efforts to improve the efficacy of CTLA-4–Ig resulted in a novel mutant form, LEA29Y (belatacept). LEA29Y is a second-generation CTLA-4–Ig molecule that differs by two amino acid residues within the ligand binding domain, resulting in increased affinity for CD80 and CD86. The resultant improvement in binding affinity led to more potent immunosuppressive properties in vitro and in vivo.[17] Belatacept has since been tested in both preclinical nonhuman primate studies and phase III clinical trials in human renal transplantation and was FDA approved for use in kidney transplantation in 2011. Seven-year clinical trial data demonstrated improved long-term outcomes with better renal function and a significant reduction in the risk of patient death and allograft loss with belatacept in a CNI-free regimen compared with CsA-based immunosuppression.[16] Higher-than-expected acute rejection rates and logistic challenges related to intravenous infusion administration requirements have slowed large-scale uptake of belatacept. A few centers have employed belatacept with low-dose tacrolimus that is tapered off within the first year of transplant or thymoglobulin induction, achieving similar acute cellular rejection rates as conventional CNI-based immunosuppression regimens while achieving the long-term improvements in allograft eGFR that is associated with belatacept therapy. Belatacept cannot be used in recipients who are naïve to EBV infection because of higher associated rates of PTLD in these patients. With proven improvement in long-term transplant outcomes and a favorable toxicity profile, along with new-generation blockers and alternative delivery methods poised for clinical testing in transplantation, the future for costimulation-based immunosuppression strategies is bright.

B-Cell– and Antibody-Directed Therapies

Intravenous immune globulin. IVIG is composed of pooled plasma fractions from thousands of donors and essentially contains a representative sample of all antibodies found within that population. It is used frequently in the treatment of several autoimmune diseases, such as idiopathic thrombocytopenic purpura, Guillain-Barré syndrome, and myasthenia gravis as well as in patients with severe immune deficiencies featuring low or absent antibody levels. IVIG is also used in organ transplantation, specifically in the treatment of humoral rejection or before transplantation in highly sensitized recipients as a desensitization method in an attempt to reduce the PRA score and risk for hyperacute or early rejection. More recently, it has also been used as part of ABO-incompatible protocols. Although the immunosuppressive mechanism of IVIG is not known, it probably works through several mechanisms to alter the immune response, including neutralization of circulating autoantibodies and alloantibodies through antiidiotypic antibodies and selective downregulation of antibody production through Fc-mediated mechanisms.[40]

Rituximab. Rituximab is a murine antihuman CD20 chimeric antibody that was initially developed for the treatment of B-cell lymphoma and has since been used in the treatment of PTLD. CD20 is a cell surface protein expressed on all mature B cells but not on plasma cells. Rituximab binds to CD20 and facilitates antibody-dependent cellular cytotoxicity and CDC of B cells and promotes programmed cell death. More recently, rituximab has been used in a wide variety of autoimmune disorders and as a component in some investigational strategies designed as induction therapy in highly sensitized transplant recipients undergoing kidney transplantation or even in ABO-incompatible pairings. Some studies have indicated a reduction in the risk of AMR and antibody rebound posttransplant with rituximab, whereas others have shown no benefit. Therefore, additional clinical studies are needed to better define its optimal role in solid organ transplantation. Interestingly, the fact that CD20 is not expressed on antibody-producing plasma cells may explain the mixed clinical results with rituximab, and its beneficial effects may relate to the role of B cells in antigen presentation and memory B cells in antibody recall responses.

Antiplasma Cell Therapies

In an effort to specifically target antibody-secreting plasma cells, the anti-CD38 mAb daratumumab and two proteasome inhibitors have emerged. In contrast to CD20, CD38 is expressed on the surface of short- and long-lived plasma cells and may be a better target for the control of AMR resulting from plasma cell–derived alloantibodies. However, daratumumab mediates potent depletion of not only plasma cells but also potentially beneficial immunoregulatory T- and B-cell subsets. Therefore, the net effect of this anti-CD38 mAb remains to be carefully investigated in human transplantation. The proteasome inhibitors bortezomib and carfilzomib also selectively target antibody-producing plasma cells because of their high rate of Ig synthesis and reliance on their proteasomes to break down damaged proteins. The use of these agents to treat AMR in transplantation has also led to mixed results, and although proteasome inhibition may be effective at controlling acute antibody production, combination with other agents may be needed to achieve sustained control of alloantibodies and improve long-term outcomes in transplantation.

Eculizumab. The complement system is one of the main components of the innate immune response but also plays a significant role in regulating the adaptive immune system. Complement activation with formation of the membrane attack complex is the end point of a number of inflammatory processes that can cause damage to the transplanted organ. In particular, the role of complement in AMR or other processes that lead to immune complex deposition within the allograft or xenograft has recently been recognized as a potential target of therapeutic intervention. Eculizumab is a humanized mAb targeting the complement component C5. Its binding to C5 inhibits the formation of complement components downstream, including the split product C5a and membrane attack complex. It is approved to treat patients with paroxysmal nocturnal hemoglobinuria and atypical hemolytic uremic syndrome. More recently, there have been several reports employing eculizumab in solid organ transplantation as a means to treat or even to prevent AMR and other complement-mediated causes of renal allograft dysfunction and injury (e.g., atypical hemolytic uremic syndrome). Some efficacy has been observed when given prophylactically in combination with plasma exchange and IVIG in highly sensitized recipients at high risk for development of AMR. Unfortunately, it has not been universally effective, as a significant number of highly sensitized patients proceed to experience AMR despite treatment. This likely reflects the complexity of the processes leading to AMR, suggesting that additional mechanisms may be at play. Additional ongoing studies have shown promising early results with other complement-specific reagents, such as an inhibitor of C1 esterase (Berinert), but further trials are needed.

Novel Immunosuppressive Agents

The vast improvements in immunosuppression and transplant outcomes have led to a very high standard for new agents to overcome. Although agents in the clinical development pipeline have had rational mechanisms of action and strong preclinical efficacy, many have not met expectations and have failed to show efficacy and improved outcomes.

Selective CD28 antagonists. Costimulatory blockade has emerged as a promising immunosuppressive strategy in transplant patients. However, belatacept (the only costimulatory blockade drug currently clinically approved for transplant immunosuppression) blocks not only the T-cell activation signals mediated through CD28 but also the immunosuppressive signals mediated by CTLA-4. Several selective CD28 antagonists were developed to target the costimulatory pathways required for T-cell activation while leaving the suppressive signals mediated by CTLA-4 intact. FR104 is an anti-CD28 monovalent Fab´ antibody. This monovalent Fab´ antibody was designed to prevent the CD28 cross-linking and resulting T-cell costimulation that would occur with divalent anti-CD28 mAb.[41] In nonhuman primate renal transplant models, FR104 was more efficacious in preventing acute cellular rejection than belatacept, with a trend toward higher frequencies of Tregs in FR104-treated animals.[42] FR104 is currently being studied in early phase kidney transplant clinical studies. Similarly, lulizumab, a pegylated anti-CD28 monovalent domain antibody (dAb), has been shown to prolong nonhuman primate renal allograft survival in sensitized recipients treated with a desensitization regimen of preoperative carfilzomib and lulizumab

CD40/CD154 pathway blockade. Beyond the CD28/B7 pathway, blockade of the CD40/CD154 costimulation pathway remains of significant interest in transplantation. Although the clinical development of CD154-specific therapies has been circuitous and challenged by an association with thromboembolic events in preclinical and clinical studies, experimentally targeting this pathway continues to show profound effects on alloimmunity. The recognition that anti-CD154 mAbs may cause thromboembolism by binding and cross-linking CD154 on platelets has spurred the pursuit of therapeutic agents that can disrupt CD40/CD154 signaling without cross-linking platelet-bound CD154. Initially efforts focused on the development of therapeutics targeting CD40, the receptor for CD154, thereby avoiding the previously seen thromboembolic complications. A few humanized anti-CD40 antibodies such as iscalimab (CFZ533) and bleselumab (ASKP1240) were developed and tested in clinical trials of patients undergoing kidney or liver transplantation. Unfortunately, development has not progressed after trials were halted because of concerns with increased rejection and/or infections. More recently, therapeutics designed to target CD154 have reemerged after alterations have rendered them Fc-silent, eliminating the potential for cross-linking of platelets and resultant thromboembolism. These Fc-silent anti-CD154 drugs include tegoprubart (AT-1501), dazodalibep (HZN-4920), and frexalimab (SAR441344). Tegoprubart is a humanized, Fc-silent anti-CD154 that is now being evaluated in a clinical trial of kidney transplant recipients. Results from this and other trials will be an important next step in realizing the potential of next-generation costimulation blockade reagents.

IL-6–directed therapies. Recently, several trials have explored the role of therapeutics targeting the IL-6 pathway to treat chronic active AMR, a common cause of late allograft loss after renal transplantation. IL-6 is a proinflammatory cytokine that has wide-ranging effects on B-cell and T-cell alloresponses. IL-6 promotes B-cell maturation into plasma cells and plays an important role in stimulating and maintaining germinal center formation and high-affinity antibody production, partly through its role as a potent stimulator of Tfh. Furthermore, IL-6 stimulates the development of proinflammatory Th17 cells while inhibiting the development and differentiation of suppressive Tregs. Interestingly, higher levels of IL-6 have been observed in rejecting human kidney, liver, and heart allografts.[43] Several groups have explored targeting the IL-6 pathway as either part of a desensitization strategy in highly sensitized transplant candidates or to treat chronic active AMR in transplant recipients. Tocilizumab, an anti–IL-6 receptor mAb, was effective in several desensitization regimens in highly sensitized transplant candidates. Several case studies have also demonstrated efficacy of tocilizumab in treating chronic active AMR, with significant reductions in DSA and stabilization of eGFR. A recent case-control series found that in lung transplant patients with chronic AMR, treatment regimens with tocilizumab had more clearance of DSA and lower rates of graft failure compared with treatment regimens without tocilizumab.[44] One phase II open-label study of clazakizumab (anti–IL-6) found that in 20 highly HLA-sensitized patients with end-stage renal disease awaiting kidney transplantation, clazakizumab along with plasma exchange and IVIG resulted in significant reduction in both class I and class II antibodies, enabling 18 of 20 patients to be successfully transplanted.[45] A recent randomized controlled clinical trial of clazakizumab in renal allograft recipients with chronic active AMR found that clazakizumab stabilized the eGFR after initiation of therapy and resulted in a significant reduction in DSA levels and C4d staining in the allografts.[46]

NOVEL THERAPIES TARGETING B CELLS AND ANTIBODIES

In addition to IL-6–directed therapies, some efforts to reduce alloantibody in highly sensitized transplant candidates have used the new drug imlifidase, a recombinant cysteine protease derived from *Streptococcus pyogenes* that can rapidly cleave all four IgG subclasses. Imlifidase binds and cleaves just below the hinge region of IgG, and the resulting fragments can no longer mediate their antibody-dependent cytotoxic effects and are rapidly cleared from circulation. Some pilot studies have demonstrated that imlifidase can successfully allow transplantation of highly sensitized recipients, although the drug is limited by a "rebound effect" of DSA that could constrain long-term transplant success. Another novel B-cell–directed therapy with investigational use in transplantation is belimumab, an mAb directed against B-cell–activating factor (BAFF). BAFF is a soluble mediator secreted by a variety of cells (including monocytes and macrophages) that interacts with BCRs such as BAFF receptor (BAFF-R), B-cell maturation antigen (BCMA), and transmembrane activator and calcium modulator and cyclophilin ligand interactor (TACI). By disrupting BAFF signaling, belimumab suppresses B-cell survival and leads to reduced numbers of circulating B cells. One small trial of belimumab in renal transplant patients has been published, and it found belimumab was a safe adjunct therapy to conventional immunosuppression, although surprisingly no expected reduction in B cells in belimumab-treated patients was noted.[47]

Complications of Immunosuppression

The development of immunosuppressive agents was the key step in the advancement of the field of transplantation. Unfortunately, these same agents are responsible for much of the morbidity associated with organ transplantation as well. All current immunosuppressants function to a greater or lesser degree in a nonspecific fashion (i.e., global immunosuppression instead of donor-specific or allospecific immunosuppression). The consequence is occasional overzealous suppression of the immune system, resulting in infectious complications, primarily viral infections, as well as an increased risk of malignant disease. In addition, many of these agents modify the function of proteins and pathways required for normal cell function, and consequently, their inhibition results in undesired, nonimmune side effects, including direct organ injury.

Risk of Infection

There is a fine balance between sufficient immunosuppression to prevent rejection and preservation of the host response to nontransplant antigens and pathogens. Introduction of tissue from one individual to another always introduces the potential for transfer of new organisms. Currently, an extensive battery of testing is performed on both the donor and recipient before transplantation. These examinations have greatly decreased the potential exposure to the recipient, but no test is perfect, and testing can be limited by available technology and the time interval between procurement and implantation. Some infections may still be transferred unknowingly for various reasons, including early infection and lack of seropositivity. Infections may be donor derived, such as a CMV-positive organ placed into a CMV-negative recipient, or may arise from less commonly transferred viruses, resulting in primary infections of HIV, hepatitis C virus, hepatitis B virus, tuberculosis, *Trypanosoma cruzi,* West Nile virus, lymphocytic choriomeningitis virus, or rabies.[48]

The threat comes not only from new pathogens but, more importantly, from those to which the recipient has likely already been exposed and harbors in a state of dormancy or latency. Normally, these pathogens are controlled after the initial infection and remain quiescent. After the immune system is rendered impotent by pharmacologic suppression, these pathogens can spring to life and quickly become uncontrollable. Recipient-derived infections are much more common after transplantation than donor-derived infections. One common example is CMV reactivation. The majority of the population has been exposed to CMV at some point in their lives. In the setting of induction and maintenance immunosuppressive therapy in transplantation, CMV reactivation can occur, resulting in pneumonitis, hepatitis, pancreatitis, or colitis. CMV has also been implicated in the lesions of heart transplant recipients with chronic rejection, highlighting the interplay between the immune response and chronic viral infections or the inflammation they may induce. Other recipient-derived infections include tuberculosis, certain parasites (*Strongyloides stercoralis*, *T. cruzi*), viruses (e.g., CMV, EBV, herpes simplex, varicella-zoster, hepatitis B, hepatitis C, and HIV), and endemic fungi (e.g., *Pneumocystis jiroveci*, *Histoplasma capsulatum*, *Coccidioides immitis*, and *Paracoccidioides brasiliensis*).

Fortunately, patterns of opportunistic infections after transplantation have been altered by the use of routine antimicrobial prophylaxis. The risk for reactivation is highest approximately 6 to 12 weeks after transplantation and again after periods of increased immunosuppression for acute rejection episodes. Transplant programs use various prophylactic regimens, depending on the organs transplanted. Many regimens include pneumococcal vaccine, hepatitis B vaccine, and trimethoprim-sulfamethoxazole for *Pneumocystis* pneumonia and urinary tract infections; ganciclovir or valganciclovir for CMV infections; and clotrimazole troche or nystatin for oral and esophageal fungal infections. As immunosuppressive strategies have evolved, resulting in increases in both allograft and patient survival, the specific pathogens as well as the pattern of infection have also evolved. For example, the polyomaviruses BK and JC have been recognized to play a more important role in transplantation than previously understood. Infection with the polyomavirus BK has been found in association with a progressive nephropathy and ureteral obstruction, and the JC virus has been associated with progressive multifocal leukoencephalopathy. Detection of BK viral DNA in blood and urine has been useful for monitoring response to therapy, which includes minimizing immunosuppression and treatment with antiviral therapies.

Risk for Malignant Disease

The immune system not only plays a critical role in defending the host against attack from pathogens, it also plays an important role in the surveillance and detection of cancer, particularly those cancers driven by viral infection. The consequence is a nearly tenfold increase in rates of malignant disease. Skin cancers, particularly squamous cell cancers, are the most common malignant conditions in transplant recipients and account for substantial morbidity and mortality.[49] As expected, virally mediated tumors tend to occur much more frequently in transplant recipients. For example, human papillomavirus is associated with cancer of the cervix, hepatitis B and C viruses with hepatocellular carcinoma, and human herpesvirus 8 with Kaposi sarcoma. EBV, in particular, can be associated with the development of PTLD, a broad term used to describe EBV-associated lymphomas that occur in transplant recipients. PTLD varies from asymptomatic to life threatening, and, accordingly, treatment varies from simple reduction or withdrawal of immunosuppression to vigorous chemotherapeutic regimens. More recently, patients have been treated with antiviral agents targeting EBV or even chemotherapy including antibody therapy against the tumor cells, such as rituximab.

Nonimmune Side Effects

Although current immunosuppressants have become increasingly more specific, in general, they are still directed at pathways that play an important role in multiple systems other than immunity. Thus, inhibition of a pathway for the sake of immunosuppression can also lead to unintended consequences if the target is critical to other processes. For example, CNIs are potent suppressors of T-cell activation, but their activity not only decreases IL-2 transcription but also increases TGF-β expression. Elevated levels of TGF-β result in an increase in endothelin expression and eventually lead to hypertension. In addition, TGF-β is thought to play a critical role in the development of chronic allograft nephropathy, previously thought to be immune mediated but now likely to be, at least partly, secondary to nonimmune side effects secondary to CNI use.

Histologic evidence of CNI-associated nephrotoxicity is essentially universal in renal transplants by 10 years. Furthermore, these deleterious effects are not limited to only renal transplant recipients. The incidence of chronic renal failure in nonrenal transplant recipients is an astonishing 16.5%.[50] New-onset diabetes after transplantation is also an important problem, particularly in individuals receiving tacrolimus or steroids. The incidence of new-onset immunosuppressive-related diabetes mellitus approaches 30% in the first 2 years after renal transplantation, conferring a significantly higher risk of death. In addition to renal failure, hypertension, and diabetes, immunosuppressive therapy can lead to hyperlipidemia, anemia, and accelerated cardiovascular disease, which is a leading cause of death in long-term transplant survivors. Thus, it appears that the very reagents that ushered in a new era of short-term success in organ transplantation have proven to be major contributors to the demise of the transplanted organ or recipient over the long term. Clearly, there is a pressing clinical need to develop novel immunosuppressive agents that are effective and more specific yet less toxic, or to devise strategies to induce immune tolerance so that long-term immunosuppression may eventually be eliminated altogether.

TOLERANCE

Immunologic tolerance, or the maintenance of allograft function without immune suppression, has been fittingly thought of as the "holy grail" of transplantation biology, as it has been the subject of noble scientific pursuit that remains a mystery and has yet to be discovered. Self-tolerance, as discussed before, involves regulation of the immune response to prevent undesired effects toward host tissues or proteins. This is established and maintained through both central (i.e., thymic selection and deletion) and peripheral mechanisms. The ability to selectively inactivate the host response toward only the transplanted donor antigens while maintaining immunocompetence would be highly desirable. This would avoid the need for lifelong immunosuppression with its associated toxicities as well as eliminate chronic rejection, a major cause of late graft failure.

It has been more than 50 years since the first reports of acquired tolerance. The discovery of neonatal transplantation tolerance has been credited to Ray Owen, a geneticist who studied the inheritance of red blood cell antigens in cattle. He reported in 1945 that dizygotic twins had mixtures of their own cells and their twin partner's cells. Earlier observations had demonstrated that bovine dizygotic twins develop a fusion of their placentas during embryonic life. This results in a common intrauterine circulation and the unabated passage of sex hormones, explaining the phenomenon of freemartin cattle. Owen also recognized that this common circulation allows the exchange of hematopoietic cells during embryonic life and the establishment of a chimeric state. Interestingly, these calves did not develop isoantibodies to their twin, suggesting a state of immunologic tolerance.

Peter Medawar acknowledged the importance of Owen's observation and predicted that an exchange of skin grafts between dizygotic calves could verify the tolerance hypothesis, and together with his postdoctoral fellow, Rupert Billingham, he performed a series of grafting experiments that provided direct support for the concept of neonatally acquired transplantation tolerance. Subsequent experiments by Billingham, Leslie Brent, and Medawar demonstrated that neonatally acquired transplantation tolerance could be achieved in mice by inoculation of embryos or intravenous injection of newborn mice with allogeneic cells. Medawar shared the Nobel Prize in 1960 for the discovery of acquired immunologic tolerance.

Just as there are multiple methods to provide for self-tolerance in any given individual, there have been many proposed strategies to induce transplantation tolerance exploiting these pathways. Some of these include clonal deletion or elimination of donor-reactive cells, clonal anergy or functional inactivation of donor-reactive cells, and regulation or suppression of donor-reactive cells. There are rare reports of patients who have discontinued immunosuppression for various reasons and have not experienced rejection. Ongoing studies within this small population of operationally tolerant patients seek to determine what mechanisms are responsible for graft maintenance in the absence of immunosuppression. One such study suggests that those kidney transplant patients who discontinue their immunosuppressive treatments for whatever reason and continue to enjoy stable allograft function also have elevated numbers of naïve and transitional B cells in their peripheral blood compared with those patients who remain on immunosuppression, suggesting a role for this cell population in the tolerant state.[51] Interestingly, several populations of regulatory B cells (Bregs) have been described by different investigators, although these are not nearly as well described as the corresponding Treg population. These Bregs often express the immunosuppressive cytokine IL-10, and many described subsets are also positive for the surface marker T-cell immunoglobulin and mucin domain 1 (TIM-1).

There are numerous reports of intentionally induced tolerance in experimental models, but most of these are not effective when translated to higher animal models such as nonhuman primates. Although there are several exciting avenues of research and even clinical trials in humans, currently there is no proven regimen to reliably induce transplantation tolerance that would be widely applicable. Here are a few strategies of particular interest that are currently under investigation.

Lymphocyte Depletion

Most currently employed immunosuppressive regimens involve the use of induction therapy. Many rely on some form of antilymphocyte preparation, most commonly RATG, to eliminate or inactivate recipient cells at the time of transplantation. They are used in the very early posttransplantation period, which corresponds to the time when ischemia and reperfusion of the graft accompanied by the surgical trauma significantly increase immune recognition. These preparations successfully remove T cells from the circulation for several days, and those that are present remain anergic for some period. Use of these agents has significantly reduced the rate of acute rejection and allowed minimization of immunosuppression in several different protocols. A number of groups have undertaken clinical trials using early recipient T-cell depletion in combination with various other immunosuppressive strategies in an attempt to induce tolerance. The prevailing concept is one of T-cell clone reduction in an effort to allow existing tolerance mechanisms to be effective. Several studies have used alemtuzumab to induce profound T-cell depletion for this purpose. Despite achieving depletion that was similar to promising preclinical studies with respect to kinetics, magnitude, and effectiveness within the secondary lymphoid tissues, treatment with alemtuzumab alone or in combination with deoxyspergualin was not sufficient to induce tolerance in adult humans.[31] Newer studies have combined alemtuzumab with belatacept and rapamycin with promising results, although tolerance was not achieved.[52] The failure of these T-cell–centric approaches suggests that other components of the immune system, such as B cells, NK cells, or monocytes, may also need to be specifically targeted to achieve tolerance. Whereas depletion alone has not been able to establish tolerance, it has allowed minimization of immunosuppression to a single agent in some cases and likely facilitates other protolerant approaches.

Costimulation Blockade

T-cell activation requires not only interaction between the TCR complex and MHC-bound peptide but also sufficient costimulatory signals to promote a successful response. TCR ligation in the absence of appropriate costimulation results in T-cell inactivation or anergy. This mechanism is used presumably as a mechanism of peripheral tolerance to control any aberrant, self-reactive T cell that may have escaped the thymic selection process. Researchers have tried to exploit this through the development of antibodies or fusion proteins designed to block these costimulatory interactions. Interruption of costimulatory pathways at the time of transplantation should thus selectively inactivate or anergize only those cells specific for donor antigen, leaving nonreactive cells unaffected. Preexisting immunity and innate responses should be unaffected by this approach. There are multiple animal models of transplantation in which this has proven to be the case, particularly with simultaneous blockade of the CD28 and CD40 pathways.[53] This approach in both rodents and primates has resulted in prolonged survival of cardiac and renal allografts without the need for any subsequent immunosuppression and without significant infectious or malignant side effects. However, the extrapolation of these results to clinical practice has been disappointing thus far. In the only human tolerance trial of costimulation blockade, hu5C8, a humanized anti-CD154 mAb, demonstrated limited efficacy and was associated with potential thromboembolic toxicity. Newly developed agents that block the CD28 pathway are now being tested as maintenance agents, which may pave the way for use in future tolerance trials. In addition, numerous other therapeutic reagents have been or are in development (such as antibodies to CD40, CD134 [OX40L], ICOS, and many other costimulatory pathways). It remains to be seen which of these will make it through the gauntlet of drug development, but there are exciting possibilities for future tolerance regimens.

Chimerism

Hematopoietic chimerism is associated with a particularly robust form of donor-specific tolerance. This approach involves both central and peripheral mechanisms for induction and maintenance of tolerance. Complete chimerism classically occurs in bone marrow transplantation where all bone marrow–derived cells in a recipient are eliminated and replaced by donor cells. However, the morbidity associated with the myeloablative conditioning required to achieve complete chimerism precludes it as a viable method of tolerance induction in solid organ transplantation. Hence, mixed chimerism refers to a recipient who possesses both self- and donor-derived hematopoietic cells after bone marrow transplantation and requires less morbid and milder forms of preconditioning to achieve. In chimeric states, similar to the normal physiologic process, donor marrow elements migrate to the thymus and participate in thymic selection, resulting in central deletion of potentially donor-reactive T cells. Presumably similar events occur within the bone marrow for B-cell selection. The peripheral compartment can be pharmacologically deleted in a nonspecific fashion at the time of transplantation, or alternatively, donor antigen delivered at the time of bone marrow infusion engages donor-reactive cells in the absence of appropriate costimulation as a result of concomitantly administered immunosuppression, causing peripheral deletion, anergy, or regulation and resulting in donor-specific nonresponsiveness.

In humans, successful bone marrow transplantation and complete chimerism allow the acceptance of subsequent organ allografts from the same donor in the absence of immunosuppression. Conventional bone marrow transplantation regimens, however, are typically myeloablative in nature, and the associated toxicities are too great for them to be employed as part of a solid organ tolerance trial. Newer advances in nonmyeloablative techniques with less toxicity have since paved the way for the clinical application and testing of mixed chimerism–based strategies. An initial trial to test the efficacy of a mixed chimerism strategy to induce tolerance was performed in highly selected patients suffering from both end-stage renal failure and multiple myeloma. These patients simultaneously received bone marrow and a kidney from an HLA-identical sibling. The regimen led to chimerism in all six patients; four had transient chimerism, and the remaining two progressed into full chimeras. Three patients remain operationally tolerant without any immunosuppression after a reported follow-up of up to 7 years. The same group of investigators reported on a similar protocol in haploidentical living related donor-recipient pairs that resulted in the successful induction of transient chimerism and tolerance. None of these patients possessed concomitant indications for bone marrow transplantation, such as multiple myeloma, as was the case in the first trial. One allograft was lost to irreversible humoral rejection, but remarkably, the other four recipients have sustained stable renal allograft function for up to 5 years after complete withdrawal of immunosuppressive drugs.[54] The conditioning regimen required resulted in profound T-, B-, and NK-cell depletion and substantial myelosuppression, leading to severe leukopenia and capillary leak syndrome. Interestingly, the biologic phenomenon that inspired the protocol, mixed chimerism, was not achieved in any patient, suggesting that the predominant effect is one of intensive induction.

Newer approaches have involved nonmyeloablative techniques combined with cell-based therapies to facilitate chimerism and tolerance induction. Cell-based therapies have consisted of a variety of different cell types, including modified hematopoietic stem cell preparations, Tregs, tolerogenic dendritic cells, and regulatory macrophages, among others. One notable phase II trial combined reduced-intensity conditioning with facilitator cell-enriched hematopoietic stem cell transplantation in HLA-mismatched living donor kidney transplant recipients. Of 31 subjects with more than 12 months of follow-up, 22 patients achieved stable donor chimerism and were weaned off immunosuppression. However, not all subjects achieved chimerism and discontinuation of immunosuppression, and several experienced recurrent autoimmunity and infectious complications resulting in graft loss.[55] Two patients developed graft-versus-host disease, resulting in one death. Therefore, although these approaches show promise for immunosuppression withdrawal in a portion of transplant recipients, the incidence and durability of tolerance, the rate and severity of graft-versus-host disease, and the long-term effects of intensive conditioning remain to be determined before these regimens find a role in clinical practice.

Adoptive Cell Transfer Therapy

Several groups have recently tried to achieve allograft tolerance through stimulation of peripheral tolerance via adoptive transfer of immunomodulatory cells. Several groups have sought to expand autologous polyclonal CD4+/CD25+/FoxP3+ Tregs and then adoptively transfer into an allograft recipient to generate durable peripheral tolerance against an allograft. This strategy has shown success in both nonhuman primate and some pilot human clinical trials, but it is generally limited by the difficulties of enriching and expanding Tregs ex vivo as well as by the less potent immunosuppressive effects of polyclonal rather than donor-specific Tregs. An alternative strategy to mitigate these difficulties is to rely on chimeric antigen receptor Tregs (CAR-Tregs). This strategy transduces autologous Tregs with the gene encoding a CAR, which recognizes donor-specific HLA molecules through a single-chain variable fragment (scFv) domain, which is a fusion protein of the variable's regions of the heavy and light chains of a donor-specific immunoglobulin. This scFv domain is usually coupled to the intracellular signaling domain of CD3ζ as well as additional intracellular costimulatory domains (such as CD28), allowing activation of the CAR-Treg after binding to donor-HLA molecules. CAR-Tregs allow the generation of a large quantity of allograft-specific Tregs, thus maximizing potential immunosuppression of alloimmunity. The STEADFAST trial is a phase I/II, first-in-human clinical trial of CAR-Tregs in recipients of living donor renal transplants, and it is currently enrolling. Finally, some investigators have also explored whether adoptive transfer of bone marrow–derived mesenchymal stem cells can confer allograft tolerance, given the well-described immunosuppressive effects of this cell population. One small pilot trial (the TRITON study) found that adoptive transfer of allogeneic mesenchymal stromal cells enabled early withdrawal of tacrolimus in many renal transplant patients without an increase in allorejection and with preserved renal function compared with a control group on conventional tacrolimus-based immunosuppression.[56]

NEW AREAS OF TRANSPLANTATION

Xenotransplantation

The most pressing problem in clinical transplantation is the shortage of available organs. More than 100,000 individuals are currently listed and awaiting organ transplantation. Several strategies have emerged to expand the available organ pool for patients with end-stage organ failure, including the dramatically increased use of matched-pairs kidney exchanges to increase the number of living donor transplants, the use of hepatitis B– or hepatitis C–infected donor organs in noninfected recipients, the use of HIV-infected donor organs in HIV-positive transplant candidates, and a significantly expanded use of organs from donors after cardiac death (abetted by improved donor organ procurement technologies such as normothermic machine perfusion and normothermic regional perfusion). Even with these developments, however, constraints of the organ supply significantly limit access to transplantation to many patients who could potentially benefit. Xenotransplantation, the use of organs from another species, has long been offered as a potential source of a nearly unlimited organ supply for transplant patients, although a host of significant immunologic, technical, and ethical barriers remain unresolved. Norman Shumway, the pioneering heart transplant surgeon at Stanford, once famously declared that "xenotransplantation is the future, and always will be." Although his pessimism has long seemed well-grounded, recent advents have poured renewed energy into the field of xenotransplantation.

Many of the earliest examples of vascularized xenotransplants were so-called *concordant xenotransplants,* using organs from closely related species, such as transplants of nonhuman primate organs into humans. In the 1960s, Keith Reemtsma of Tulane University performed a series of 13 chimpanzee kidney transplants into patients; although most patients died within 1 to 2 months, one of the patients lived for 9 months and even returned to work as a schoolteacher. Several other early pioneers in transplant, such as Tom Starzl (who performed the first successful human liver *allo*transplant) and James Hardy (who performed the first successful human lung *allo*transplant), also experimented with xenotransplants using primate organs, but with abysmal results. Perhaps the most famous early example of concordant xenotransplant was the "Baby Fae" case, where Dr. Leonard Bailey transplanted a baboon heart into a female infant with left hypoplastic heart syndrome in 1983.[57] This transplant attracted significant coverage in the lay media, and although technically successful, the patient died of acute rejection on postoperative day 20. Besides the lack of long-term survival in these early case series, the use of concordant xenotransplants is significantly limited by the fact that the need for donor organs far outstrips the available supply of nonhuman primates, potent ethical concerns about using primates as organ donors (given the close evolutionary link between humans and primates), and concerns that zoonotic viral transmission between primates and humans poses a threat that would outweigh the benefits of transplantation on a societal level. Given these factors, it is unlikely that concordant xenotransplantation will ever gain widespread application.

Most of the recent investigations of xenotransplantation have pursued discordant xenografts—transplantation between dissimilar species—most often using porcine donors. Pigs offer many advantages for xenotransplantation compared with nonhuman primates: they are better size matched for most adult humans compared with primates, there is an abundant worldwide supply of pigs, and there are far fewer ethical concerns regarding use of porcine organs (given that pigs have been raised for human consumption for millennia). However, discordant xenografts do pose more significant immunologic barriers, mainly because of the differential carbohydrate expression on the cell surfaces of pig cells compared with humans. Specifically, pigs possess an α(1-3)-galactosyltransferase enzyme (GGTA1) and therefore express galactose-α-1,3-galactose (also known as α-Gal) sugar moieties on most cell surfaces. As humans lack this enzyme, they have a high degree of preformed IgM antibodies against cell surface carbohydrate moieties, particularly α-Gal. These so-called *natural antibodies* are similar to those antibodies that define the blood group antigens. In transplantation, they bind to the endothelial cells on the donor organ and induce a hyperacute rejection in concert with complement, precipitating an irreversible reaction of cell damage, thrombosis, and immediate graft failure. As with concordant xenografts, the remainder of the acquired and innate immune responses may also play an important role in the rejection process.

A major advance in the field of xenotransplantation was the development of genetic knockout pigs that lack the GGTA1 gene encoding α(1-3)-galactosyltransferase in 2002, which significantly extended the function of xenograft hearts in a pig-to-primate preclinical transplant model (Fig. 49.26).[58] The advent of CRISPR/Cas9 transgenic techniques and refinement of somatic cell nuclear transfer enabled the generation of pigs possessing multiple genetic manipulations intended to prolong xenograft survival. Some of these manipulations delete other genes (such as *β4GalNT2* and *CMAH*) that produce non-Gal cell-surface glycans that are targets for human natural antibodies, thereby reducing the risks of hyperacute rejection. Other genetic manipulations added transgenic human complement-regulatory proteins such as human decay-accelerating factor (hDAF; CD55) and membrane cofactor protein (MCP; CD46), transgenes intended to quell xenorejection such as inhibitory HLA-E or HLA-G, and transgenes for human coagulation regulatory proteins such as thrombomodulin and endothelial protein C receptor (as many groups had observed a posttransplant thrombotic microangiopathy in xenograft organs, which was attributed to the inability of porcine regulatory proteins to interact with human thrombin and protein C). Finally, some groups used CRISPR/Cas9 to knock out the loci of porcine endogenous retroviruses (PERVs), which were the most concerning zoonotic infections that could theoretically infect recipients of porcine xenotransplants. Recently, a commercial company published their work generating a pig for use as a xenotransplant donor with 69 distinct genetic manipulations and demonstrated up to 2 years of renal xenograft survival using these donor pigs in a nonhuman primate model and clinically relevant immunosuppression.[59] Bolstered by recent rapid advances in the field and demonstrated long-term survival in pig-to-primate preclinical transplant models, investigators at the University of Alabama-Birmingham and NYU Langone Health have used a human decedent model to approach a step closer to human clinical trials of xenotransplantation.[60] In these human decedent models, the families of brain-dead patients who are otherwise deemed not acceptable organ donors consent to have porcine xenograft kidneys or hearts transplanted into their loved ones, who continue to receive mechanical life support therapy for the duration of the experiment. Although the initial experiences with this decedent model were only for 54 to 72 hours, recently these institutions have extended the experiment for up to 2 months to better study the xenogeneic rejection responses. Investigators at the University of Maryland have now performed two life-sustaining porcine xenograft heart transplants in human patients who were otherwise not candidates for an allogeneic heart transplant. The first patient lived almost 2 months before succumbing, potentially because of an unrecognized porcine CMV in the donor heart (Fig. 49.27). The second patient died after almost 6 weeks from rejection, highlighting that significant challenges remain. Most recently, researchers at Massachusetts General Hospital transplanted a genetically modified porcine kidney into a patient whose dialysis access was failing. These early attempts of xenotransplantation into living patients have been approved by the FDA through their compassionate use exemption, but the field awaits the results of clinical trials before deciding whether the promise of widespread xenotransplantation to solve the organ shortage crisis can be realized.

Machine Perfusion

The shortage of available organs for transplant and the resulting burgeoning transplant waitlist is certainly one of the central challenges in transplantation today. One strategy to expand the supply of organs is to use normothermic machine perfusion of “marginal” organs that would otherwise be discarded, providing diagnostic or prognostic data and/or rehabilitating them and rendering them suitable for transplantation. These “marginal” organs might come from donors after circulatory death (DCDs), older donors, or steatotic donors (in the case of liver allografts). Both hypothermic and normothermic machine perfusion systems have been described, and there are conflicting data in the literature about which approach is superior. Use of machine perfusion helps minimize the ischemia-reperfusion injury that often accompanies prolonged cold static storage of organs in ice, greatly expanding the window of time in which the organs can be safely transplanted. Furthermore, machine perfusion systems also provide dynamic assessment of organ function by measurement of pH and lactate in the perfusion fluid of the machine, providing assurance that a marginal organ will not be a primary nonfunction (which would have particularly devastating consequences for organs such as the heart, lungs, and liver). Finally, there is some evidence that machine perfusion can remediate compromised allografts, allowing their posttransplant function to improve. Whereas DCDs were previously rarely employed in thoracic transplant, widespread use of machine perfusion has significantly expanded the supply and use of DCD heart and lung allografts in recent years. The advent of machine perfusion has also led to a recent dramatic expansion in the number of liver transplants performed using donors after cardiac death, as data from the International Randomized Trial to Evaluate the Effectiveness of the Portable Organ Care System (OCS) Liver for Preserving and Assessing Donor Livers for Transplantation (PROTECT trial) suggest that pumped livers have a lower incidence of early allograft dysfunction and lower

FIGURE 49.26 Advances in xenotransplantation. Using modern gene editing techniques such as CRISPR-Cas9, cloned pigs can be developed bearing multiple genetic modulations intended to render them better donors for xenotransplantation. Many of these genetic modifications target enzymes involved in creating cell surface carbohydrate moieties not present on human tissues, such as α-1,3-galactosyltransferase *(GGTA1),* beta-1,4-*N*-acetyl-galactosaminyl transferase *(B4GALNT),* and cytidine monophosphate-*N*-acetylneuraminic acid hydroxylase *(CMAH).* These carbohydrates are prominent targets for natural antibodies that can provoke hyperacute rejection of xenografts. These genetically modified pigs have been used in preclinical transplant studies with nonhuman primate recipients, demonstrating substantially longer xenograft survival than historical experiments using nonmodified porcine donors. This success has led to several recent trials of xenografts in both human decedent models (where xenografts are transplanted into brain-dead human recipients who are kept alive with life support for the duration of experiment) and even some recent compassionate-use cases where porcine hearts were transplanted into human patients. *GM,* Genetically modified; *NHP,* nonhuman primate. incidence of ischemic biliary strictures compared with allografts kept in cold static storage (Fig. 49.28).

Bioartificial Organs

The shortfall in organ availability has also led some investigators to explore the possibility that bioartificial organs might offer a new organ supply. Various bioengineering techniques have been employed to generate these bioartificial organs. Driven by the 3D printing revolution that has transformed many industries, some are exploring whether 3D bioprinting is a possibility, using microfluidics to "print" specific cells on a scaffold substrate in a bioreactor, thereby recapitulating tissues of interest. Currently, this technology is in its infancy. Another more developed strategy to develop bioartificial organs relies on decellularization of existing organs (such as organs recovered from donors but found to be unsuitable for transplant) by perfusing them with a detergent solution (usually sodium dodecyl sulfate). This decellularization leaves behind an extracellular matrix protein "scaffold" that can then be recellularized by perfusing it with a slurry of stem cells that help reconstitute a functioning organ. This strategy has been employed in porcine transplant models, showing transient function of bioartificial hearts, lungs, and renal allografts. The long-term survival of these bioartificial organs has not been observed, so it remains to be determined whether xenotransplantation or bioartificial organs might be the best ultimate strategy to expand our current organ supply.

Impact of portable normothermic blood-based machine perfusion on outcomes of liver transplant: the OCS Liver PROTECT Randomized Clinical Trial. *JAMA Surg.* 2022;157[3]:189-198.)

CONCLUSION

More than a half-century has passed since the first successful solid organ transplantation. Today, thousands of patients with end-stage diseases undergo lifesaving transplantation each year. That which was once considered impossible is now an everyday occurrence, and most transplant recipients are leading healthy, productive lives with an organ from another individual functioning inside of them. The idea of replacing a diseased organ with a healthy one is simple in concept, yet the details of managing the rejection response is complex. The immune system typically generates a highly organized yet regulated response when challenged. Many of the principal details of the normal immune response were described by researchers examining the mechanisms of allograft rejection. In fact, surgeons garnered multiple Noble Prizes in Medicine for their significant contributions to the field. Whereas short-term allograft survival rates have steadily improved, long-term outcomes remain an area in need of significant improvement. The availability of adequate donor organs remains the most pressing issue restricting the majority of potential recipients from receiving a life-sustaining transplant. There continues to be progress in xenotransplantation and tissue engineering, and they may yet provide for an unlimited supply of safe, transplantable organs. There are significant drawbacks to current nonselective immunosuppressive therapies, such as increased risks of infections and malignant disease, economic constraints, and long-term metabolic toxicities, including renal insufficiency, diabetes, hyperlipidemia, and cardiovascular disease. Increasingly targeted immunosuppressive agents continue to be developed and tested. Ultimately, the goal is to achieve low-risk, donor-specific immunosuppression. The development of a safe, widely applicable regimen that reliably produces transplantation tolerance would eliminate many of the problems currently associated with organ transplantation. Indeed, one of the medical miracles of the last century has been the success and growth of organ transplantation. Although challenges remain, transplant surgeons and scientists will undoubtedly continue to be at the forefront of discovery and innovation as the field marches forward.

CHAPTER 50

Regenerative Medicine and Its Applications to Surgery

Mitchell R. Ladd and Anthony Atala

OUTLINE

Introduction
A Brief History
Potential Impact of Regenerative Medicine
Cell Sources
Biomaterials
Engineering Tissues and Organs for Clinical Use
Clinical Applications of Regenerative Medicine Technologies
Challenges in Regenerative Medicine
Conclusion

INTRODUCTION

Regenerative medicine is defined by Nature.com as "the branch of medicine that develops methods to regrow, repair or replace damaged or diseased cells, organs or tissues. Regenerative medicine includes the generation and use of therapeutic stem cells, tissue engineering and the production of artificial organs."[1] Regenerative medicine is an exciting, growing, and interdisciplinary field that has its roots in surgery. Regenerative medicine incorporates many other fields as well, such as engineering, biomaterials, cell biology, physiology, veterinary medicine, genetics, biochemistry, and computer science (Fig. 50.1). Tissue engineering is a subset of regenerative medicine that typically combines a cell source with a three-dimensional (3D) scaffold to engineer a tissue or organ.

In this chapter, we will briefly cover the history of regenerative medicine and its potential impact on society and medicine. We will discuss the individual components of regenerative medicine that can be used alone or in combination, methods of developing or fabricating these regenerative medicine solutions, regenerative medicine therapies already in use or in clinical trials, and, finally, the many challenges the field must still overcome before regenerative medicine becomes a standard part of the surgeon's toolbox for treating patients.

A BRIEF HISTORY

The surgical origins of regenerative medicine date back to the publication of *The Culture of Organs* by Alexis Carrel and Charles Lindbergh in 1938.[2] In the late 1960s, surgeons, in particular John Burke, began working with engineers and cell biologists to engineer temporary skin replacements for treating large burns.[3,4] Since that time, the field of regenerative medicine has grown exponentially and has resulted in translation of numerous therapies to the care of patients.

POTENTIAL IMPACT OF REGENERATIVE MEDICINE

Regenerative medicine holds the potential to change healthcare. This is true not only in the realm of treating patients but also in reducing overall healthcare costs in the long term. Many diseases that regenerative medicine strives to treat are chronic, such as kidney failure or heart failure, with a US prevalence of 6.9 million and 807,920, and a total yearly expenditure of $215 billion and up to $81 billion, respectively.[5–7] It is estimated that the size of the regenerative medicine market reached $9.8 billion in 2021 and that it will reach $37.92 billion by 2030, with a compound annual growth rate of 16.2% (Fig. 50.2).[8]

For organ failure, organ transplant has, in most cases, become the gold standard treatment. Transplantation is limited by an organ shortage, which is the main impetus for the development of regenerative medicine. If regenerative medicine can help manage chronic disease, overall healthcare costs may decrease over time, even if the treatments themselves are expensive. Moreover, if these therapies can be developed using the patient's own cells or DNA, the need for lifelong immunosuppression may be obviated, further decreasing healthcare costs in the long term.

CELL SOURCES

A key component of regenerative medicine therapies is cells. Numerous options for cell sources exist, and each has advantages and disadvantages. Here we will briefly describe each cell type, along with their pros and cons (Table 50.1). For a more detailed discussion of cell sources in regenerative medicine, the interested reader is referred to the comprehensive textbook *Principles of Regenerative Medicine,* which has numerous chapters on the subject.[9]

Embryonic stem cells (ESCs), derived from fertilized eggs, are self-renewing and can differentiate into any germ cell layer (endoderm, mesoderm, or ectoderm), which makes them particularly attractive for regenerative medicine applications.[10] Unfortunately,

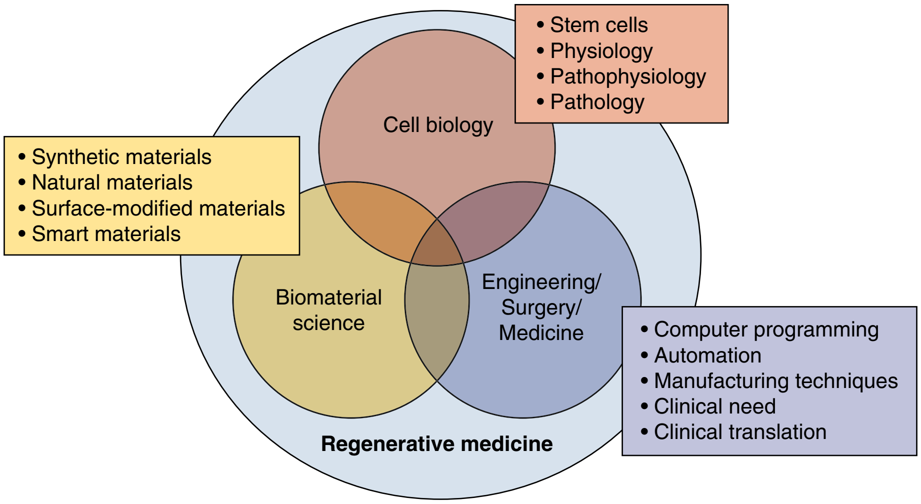

FIGURE 50.1 Regenerative medicine is a diverse and interdisciplinary field that involves cell biology, biomaterial science, and multiple practitioners—engineers, surgeons, and medical doctors.

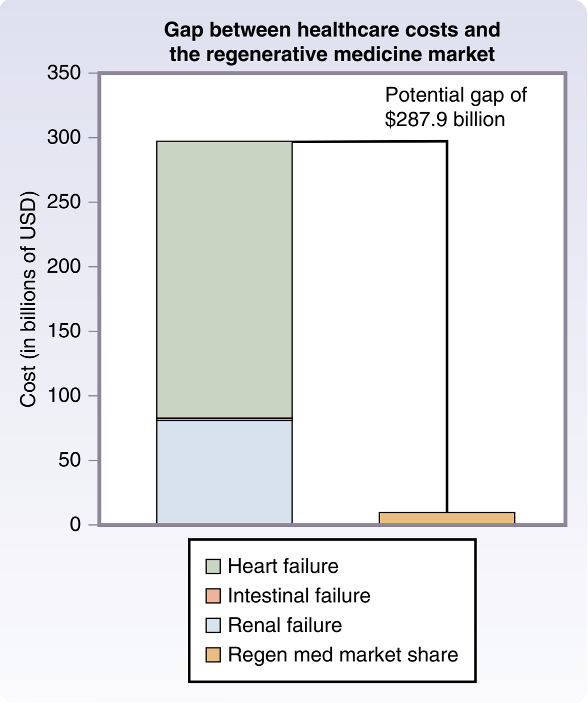

FIGURE 50.2 Healthcare costs of three chronic diseases (heart failure, intestinal failure, and renal failure) compared with the current estimated market share for regenerative medicine. Clearly, there is untapped commercial and cost-saving potential, given the gap between healthcare costs and commercial market share. *Regen med,* Regenerative medicine. (Data collated from references 5 to 8, 75, 76.)

ESCs tend to form teratomas in vivo and are shrouded in ongoing ethical debate.[10] Induced pluripotent stem cells (iPSCs) are a unique type of stem cell that was discovered in 2006 in mice and in 2007 in humans by Yamanaka and Takahashi, whereby adult somatic cells are reprogrammed back to an embryonic phenotype by introducing several transcription factors into the cell, such as Oct-3/4, Sox2, Klf4, and c-Myc.[11,12] iPSCs behave similarly to ESCs, but they lack the ethical controversy. Unfortunately, iPSCs retain their tendency to form tumors in vivo.

Amniotic fluid and placenta contain stem cells that are considered highly multipotent because they are able to differentiate into all three germ layers and are also able to self-renew as they preserve their telomere length, but unlike ESCs and iPSCs, they do not form tumors after implantation in vivo.[13] Interestingly, mesenchymal stem cells (MSCs) are also found in amniotic fluid (AFMSCs) and can differentiate into mesodermal lineages, but they can also be reprogrammed into iPSCs with a higher capacity and more rapid conversion than fully adult somatic cells such as fibroblasts.[13]

MSCs have a limited self-renewing capacity because they observe Hayflick's limit of only about 40 population doublings in terms of expansion and have the ability to differentiate into mesodermal lineages (muscle, bone, cartilage). MSCs, typically called *adult stem cells,* can be isolated from many different tissues, including bone marrow, adipose, muscle, skin, periosteum, tendon, and neural tissues.[14] MSCs are thought to derive from pericytes, or cells that are closely related to the microvasculature, which explains why they can be isolated from so many different tissues.[14] MSCs also serve as a source of secretory factors—that is, factors that are overall antiinflammatory—to create a regenerative environment for healing. MSCs have been used in numerous clinical trials, although most of them have been outside the United States.[14] Once injected, they are rapidly cleared from the body within a few days.

Adult progenitor stem cells are a type of stem cell that is further differentiated.[15] Their main role in each tissue is to maintain cell turnover and repair the tissue in which they reside.[15] Thus, they must be capable of self-renewing by generating at least one daughter cell that is a stem cell and a second cell capable of differentiating into the necessary cell lines involved in their resident tissue.[15] Many tissue-specific adult progenitor stem cells have been described—including in tissues previously thought not to contain progenitor cells—such as heart, brain, liver, pancreas, and bladder.[9] Each of these progenitor cells has been used and tested in attempts to regenerate the tissue from which they are derived.

BIOMATERIALS

Biomaterials are a critical component of regenerative medicine, in particular, tissue engineering. In the late 1960s, Burke and Yannas

TABLE 50.1 **Characterization, Similarities, and Differences Among Stem Cell Populations**

	ESCs	iPSCs	AFSCs	MSCs	ASCs
Ethical concerns	Yes	No	No	No	No
Tumorigenesis	Yes	Yes	No	No	No
Mass production	Difficult	Difficult	Easy	Easy	Moderate
Immunogenicity	High	High	Extremely low	Extremely low	Low
Differentiation potential	Very high	Very high	High	Low	Very low
Expansion potential	Very high	Very high	High	Low	Low

began developing scaffolds from natural extracellular matrix (ECM) proteins for the purposes of skin regeneration in the setting of large burns.[3] Later, in the 1980s, biodegradable polymers were introduced for seeding cells.[16,17] Clearly, whether synthetic or naturally derived, biomaterials are a key component of tissue-engineered constructs.

The range of biomaterials used for tissue engineering is as diverse as the tissues in the human body. The type and properties of the biomaterial used depend on the tissue being engineered. In general, tissue engineers prefer to have a biodegradable scaffold so that the body can regenerate tissue without chronic inflammation, but there are a few circumstances in which permanent materials are being tested for bone tissue engineering applications.[18] An ideal biomaterial would provide the appropriate structure, strength, and degradation rate such that it would provide the 3D configuration of the tissue being engineered until the cells can lay down their own ECM. The ideal material would cause minimal to no acute or chronic inflammation and would degrade in such a way as to avoid the development of a foreign body reaction that might interfere with tissue regeneration.[19]

The material to be used for an engineered tissue depends in large part on the application. When deciding on a material, one considers numerous properties: mechanical strength, surface topography, ability for cells to attach and grow, degradation mechanism, and degradation kinetics, among many others. Generally, tissue engineers aim to match the mechanical properties of the tissue they are trying to form. Thus, for muscle, one would choose a softer, more elastic material. For bone, one would choose a much stiffer, harder, tougher material. Examples of the mechanical properties of several materials, as well as the relative stiffness of tissues, are displayed in Fig. 50.3.

Biomaterials can be categorized as synthetic or natural (Fig. 50.4). Synthetic materials available are numerous and consist of certain hydrogels and polymers. Some polymers used in tissue engineering that may be familiar to the surgeon are polyglactin (or poly-lactic-co-glycolic acid) and polydioxanone, which are the polymers used to make Vicryl (Ethicon, Bridgewater, NJ) and PDS (Ethicon, Bridgewater, NJ) sutures. Natural materials can be derived from ECM proteins of mammals or other areas of biology. Examples of these types of materials include collagen, hyaluronic acid, elastin, chitin, agarose, and silk, as well as decellularized ECMs from tissues such as small intestinal submucosa, skin, and solid organs. These materials can be available in various forms, including sheets, solid structures, powders, and gels. Many natural materials capable of making gels can be used as bioink for bioprinting. In addition, natural and synthetic polymers may be blended, depending on compatibility and design needs. Finally, both synthetic and natural materials can be modified or designed to release bioactive chemicals, proteins, or drugs or have them attached to their surface. These bioactive molecules can be designed for many purposes, such as modulating the inflammatory response, providing growth factors for seeded cells, or re-creating a regenerative environment for attracting cells in vivo.[20–23]

ENGINEERING TISSUES AND ORGANS FOR CLINICAL USE

There are numerous combinations of biomaterials, scaffold fabrication techniques, and cells used to engineer and regenerate tissues and organs. These constructs can also be made with different intents, such as creating an organ-on-a-chip or body-on-a-chip for high-throughput drug screening, creating patient-specific cancer tissue organoids for evaluating chemotherapy effectiveness, treating a chronic disease, or creating an organ or tissue for transplant. Many constructs also require ex vivo preconditioning in bioreactors before implantation. Here, we will focus on a few of the most common techniques used to fabricate scaffolds and tissue constructs and prepare tissues for implantation. For more details regarding all of these processes, the reader is again referred to the excellent textbook *Principles of Regenerative Medicine*.[9]

As alluded to in the previous section, biomaterials can be fabricated into gels, porous materials using solvent-casting with pore leaching, sheets using gas foaming, porous blocks via phase separation and freeze drying, nonwoven fibrous sheets, woven fibrous mats, and numerous shapes and topographies via cast and reverse molding.[24–26] For details on any of these techniques, the reader is referred to the three excellent reviews referenced here.[24–26] Three techniques for obtaining scaffolds that warrant a deeper discussion are decellularization, electrospinning, and bioprinting.[27–30] Electrospinning is the oldest of the three techniques; it was initially invented in the early 20th century by the textile industry (see Fig. 50.6).[28] Electrospinning uses synthetic or natural polymers dissolved in a highly volatile organic solvent that is extruded through a blunt-tip needle by a syringe pump. An extremely high voltage, on the order of kilovolts, is applied to the needle, and the electric forces overcome the surface tension forces to cause the polymer to precipitate and whip toward a grounded mandrel, resulting in a mat of nanofiber-scale fibers. This technique was initially abandoned by the textile industry because it was not very practical, but because of its ability to make nanofibers, the technique was adopted by tissue engineers in the late 20th and early 21st centuries. One approach for engineering solid organs is to

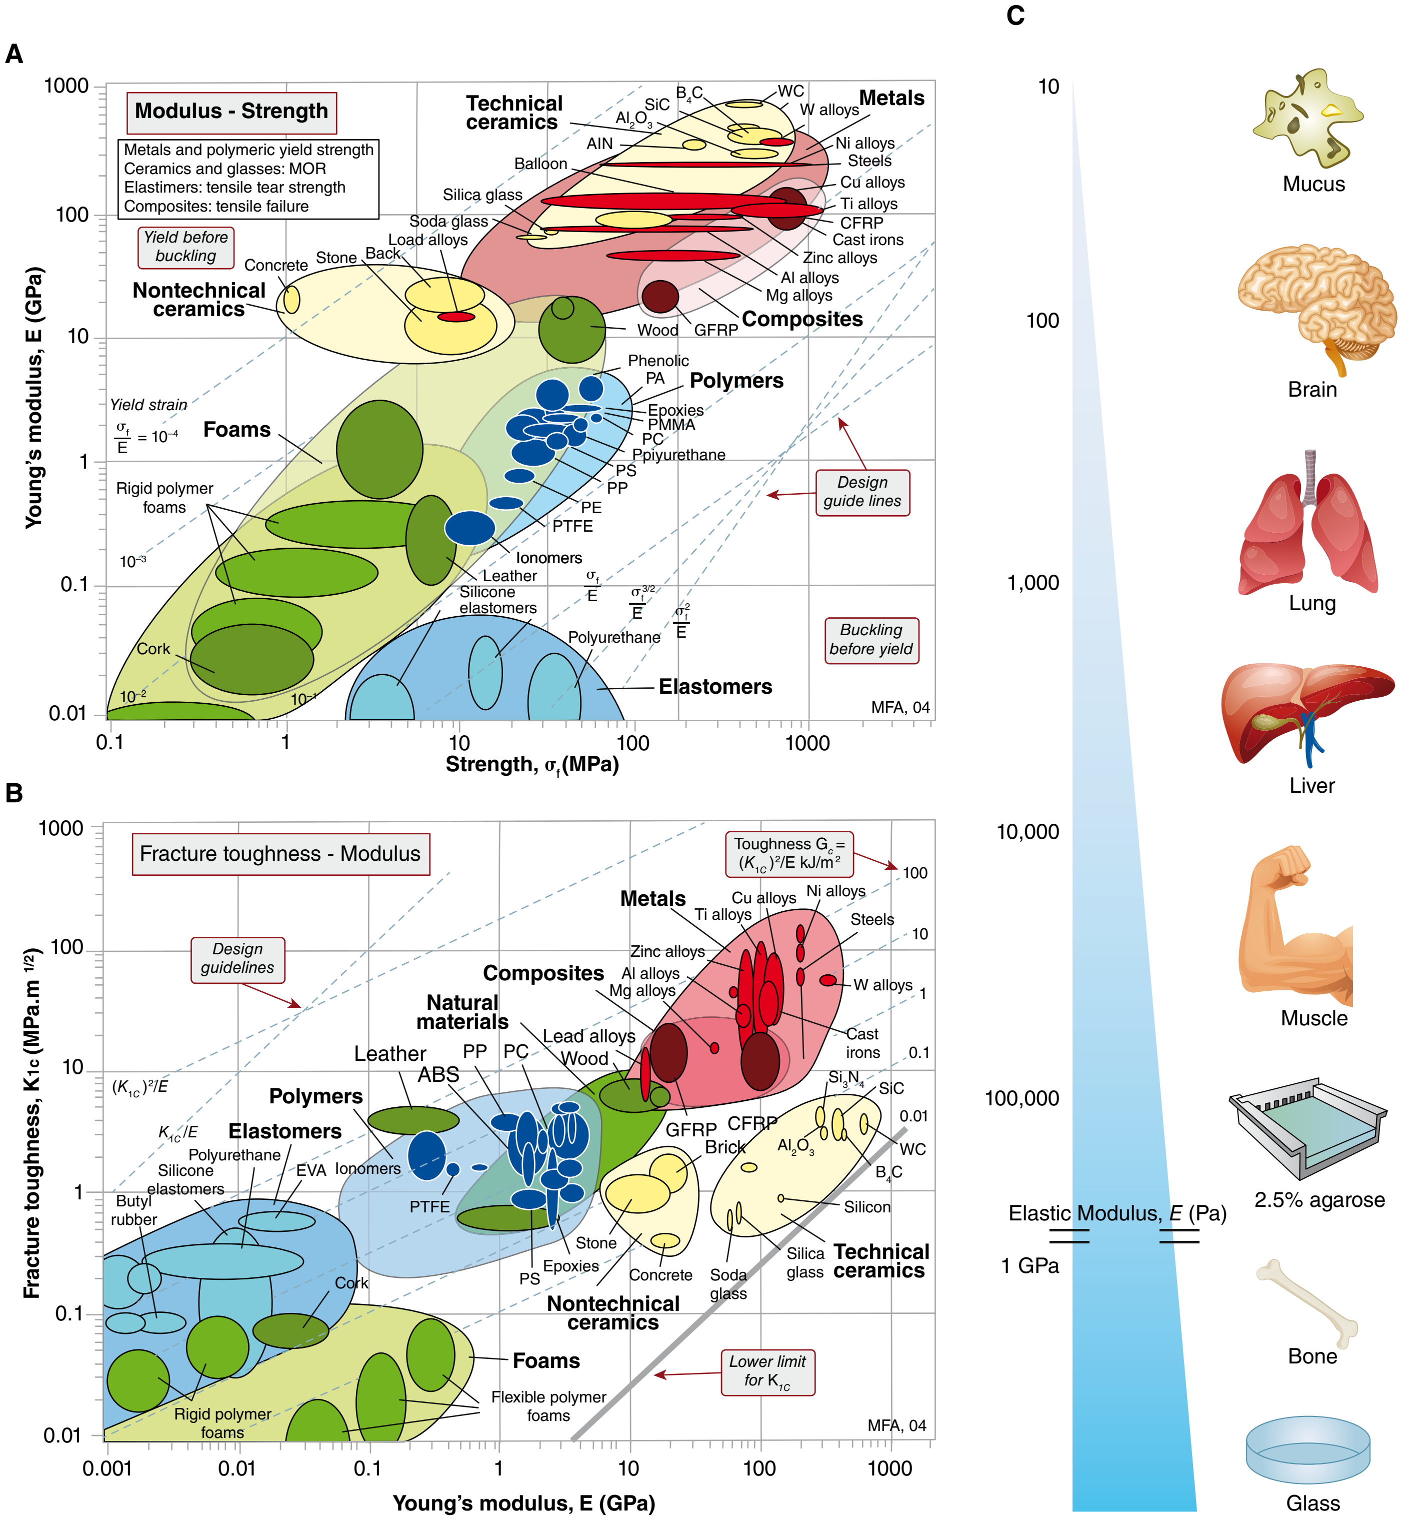

FIGURE 50.3 Ashby chart comparing different mechanical properties between materials. (A) Modulus versus strength. (B) Toughness versus modulus. (C) Elastic modulus of various tissues. *CFRP*, Carbon fiber-reinforced thermoplastic; *EVA*, ethylene(vinyl acetate); *GFRP*, glass fiber-reinforced plastic; *MOR*, modulus of rupture; *PA*, phosphatidic acid; *PC*, phosphatidylcholine; *PE*, phosphatidylethanolamine; *PMMA*, poly(methyl methacrylate); *PP*, polypropylene; *PS*, phosphatidylserine; *PTFE*, polytetrafluoroethylene; *WC*, water cosolvent. (Adapted from Zhu Y, Wagner WR. Design principles in biomaterials and scaffolds. In: Atala A, Lanza R, Mikos AG, Nerem R, eds. *Principles of Regenerative Medicine*. St. Louis: Elsevier; 2019:505-522.)

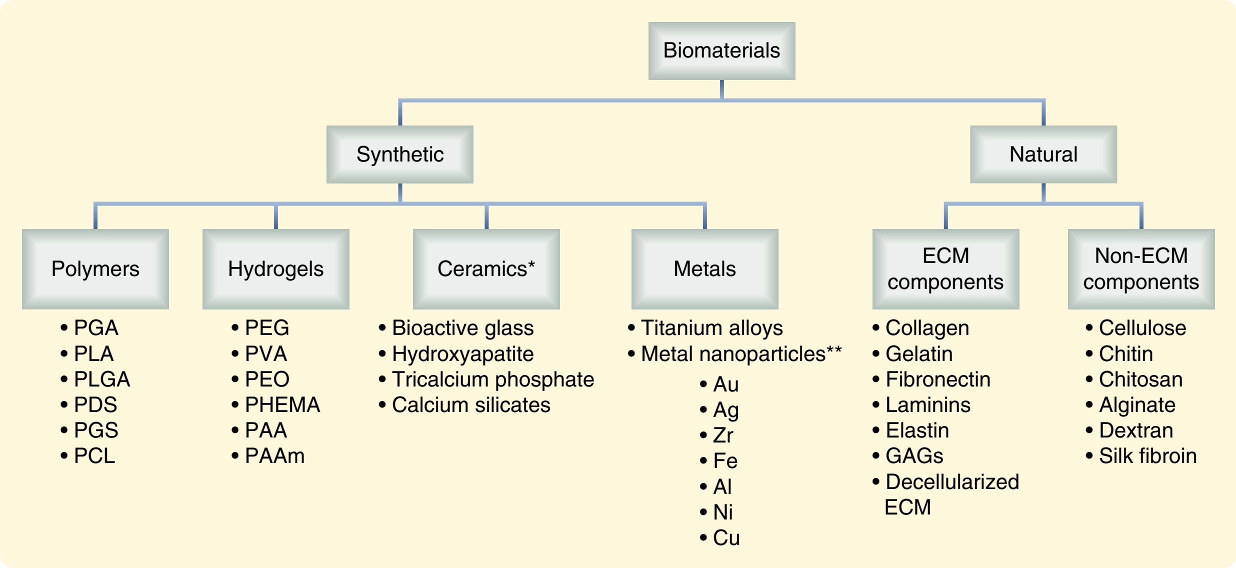

FIGURE 50.4 An overview of commonly used biomaterials in tissue engineering and regenerative medicine compiled from references 18, 22, and 77 to 80. The materials listed here are not exhaustive. *Ceramics are more difficult to characterize as synthetic versus natural—bioactive glass and calcium silicate are synthetic; however, the other ceramics do occur naturally in bone, or their constituents do (e.g., hydroxyapatite and tricalcium phosphate). **Aside from titanium alloys that are used in bone tissue engineering, few metal-based scaffolds are used; more commonly, metal nanoparticles are used alone or as additives to other materials to modify the properties of the base scaffold. For instance, Ag can imbue a scaffold with antimicrobial properties. *Ag*, Silver; *Al*, aluminum; *Au*, gold; *Cu*, copper; *ECM,* extracellular matrix; *Fe*, iron; *GAGs*, glycosaminoglycans; *Ni*, nickel; *PAA*, poly (acrylic acid); *PAAm*, poly (acrylamide); *PCL*, polycaprolactone; *PDS*, polydioxanone; *PEG*, polyethylene glycol; *PEO*, polyethylene oxide, *PGA*, polyglycolic acid; *PGS*, polyglycerol sebacate; *PHEMA*, poly (2-hydroxyethyl methacrylate); *PLA*, polylactic acid; *PLGA*, polylactic-co-glycolic acid; *PVA*, polyvinyl alcohol; *Zr*, zirconium.

decellularize donor tissues. In this approach, the cells and DNA from native tissue are completely removed by perfusing a series of gentle detergent washes, leaving behind the 3D anatomy of the tissue of interest as well as the microarchitecture. The scaffolds can then be repopulated with cells. This strategy was first demonstrated with penile corporal cavernosa tissue, showing the first experimental creation of a functional solid organ in preclinical animal models.[31–33] Tissue-engineered penile tissue has been successful in a phase I clinical trial and has been approved by the FDA.[34,35] Perfusion techniques through the vasculature for both decellularization and recellularization have also been demonstrated (Fig. 50.5).[27,36,37] A more recent development is bioprinting.[30] Bioprinting can be achieved by several methods (Fig. 50.6), but all of them involve placing the cells of interest in a "bioink" (typically a gel in liquid form that solidifies after printing) and using computer-aided programs to print the cells and scaffold materials in the desired 3D conformation (see properties of bioinks in Fig. 50.6). Bioprinting has garnered a lot of attention because it has the potential to be an enabling technology in tissue engineering and regenerative medicine. That is, bioprinting will allow for personalized constructs in previously difficult-to-fabricate dimensions, consistent fabrication, and high throughput as a result of automation, and it will potentially allow these technologies to be manufactured and scaled in an efficient way.[30] These are important challenges to overcome if regenerative medicine is to be translated into clinical practice, and they will be discussed further in a later section.

Once a scaffold has been fabricated, cells are applied to the scaffolds. Historically, this was done via static seeding; that is, the cells were dripped onto the scaffold in high concentration and allowed to attach. Bioprinting has emerged as an automated and consistent way to apply cells to scaffolds.

Before implantation, some tissues benefit from preconditioning in a bioreactor. Bioreactors are used to re-create the in vivo environment to better prepare engineered constructs for implantation. By re-creating this environment, constructs can generally mature to better recapitulate their intended organ before being transplanted.[38] One of the earliest examples of bioreactor use in tissue engineering was for tissue-engineered blood vessels.[39] Using the pulsatile blood vessel bioreactor (a more recent example is shown in Fig. 50.7) resulted in engineered blood vessels that more closely resembled native blood vessels compared with control engineered blood vessels that were not exposed to pulsatile flow.[39] Bioreactors have been created for numerous tissue types and are most often used to help improve cell viability by providing flow through vascular-like channels.[38] Additionally, bioreactors are used, as described with the engineered blood vessel, to mimic the in vivo environment for engineered organs so that, ideally, fully developed organs can be prepared for transplant.[38]

CLINICAL APPLICATIONS OF REGENERATIVE MEDICINE TECHNOLOGIES

Regenerative medicine has the lofty goal of being able to regenerate all tissues and organs so that it can prolong the healthy lives of humans. Although the field is far from reaching this goal, there are lots of exciting and promising investigations underway. More

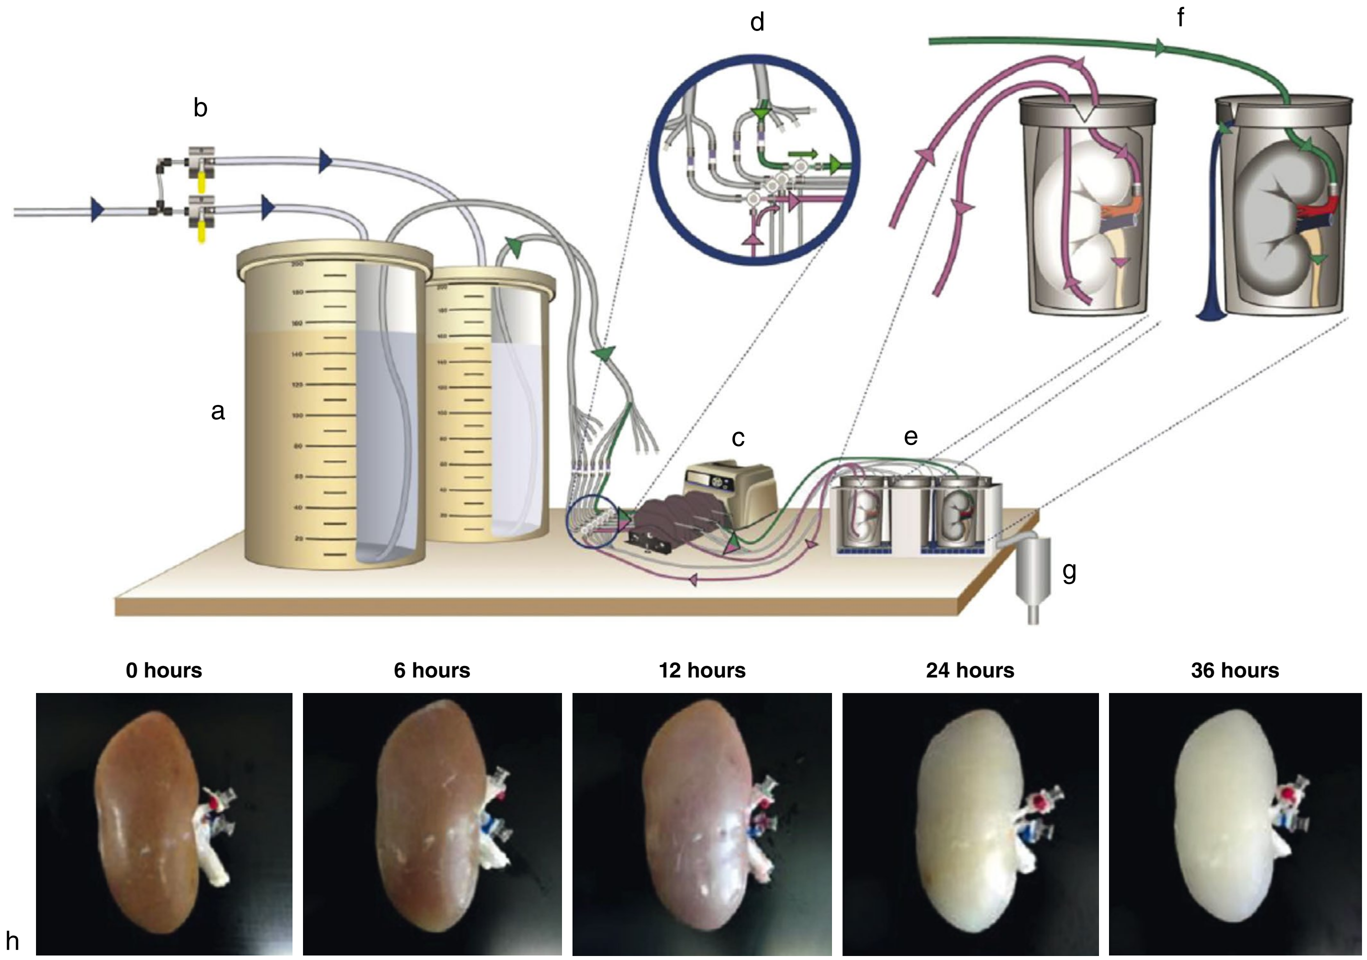

FIGURE 50.5 An example setup for a perfusion decellularization chamber for whole-organ decellularization (in this case, kidney). In brief, *a* is the wash buffer tank in which the detergent solution is placed that is then diluted by water from *b*. This runs through a peristaltic pump *(c)*. Upstream of the pump is a series of interchangeable three-way stopcocks *(d)* to route the perfusate to any number of organ chambers *(e)*. The perfusate is then perfused through the renal artery and collected from the renal vein and ureter. Overflow is then either recirculated, as in the left side of *f*, or discarded into a drain *(g)*, as in the right side of *f*. In *h*, you can see the dramatic change in the kidney from time 0 to the end of the decellularization process at 36 hours. (Adapted from Sullivan DC, Mirmalek-Sani SH, Deegan DB, et al. Decellularization methods of porcine kidneys for whole organ engineering using a high-throughput system. *Biomaterials*. 2012;33[31]:7756-7764.)

importantly, regenerative medicine has brought several therapies and products to clinical trials and the marketplace, and we aim to summarize some of these successes relevant to general surgery here. A detailed discussion of every technology is outside the scope of this chapter. For a more detailed discussion of each tissue and organ type, the reader is again referred to the excellent text *Principles of Regenerative Medicine,* in addition to a recent review of tissue engineering for pediatric applications titled "Regenerative Medicine: Postnatal Approaches."[9,40]

The first clinical application of tissue engineering was for temporary skin barriers for large burns and wound healing. These therapies were used as biologic wound dressings pending sufficient skin growth in other sites in the patient's body that could be harvested and grafted as permanent replacements. These efforts were pioneered by three groups: Burke and Yannas, whose efforts resulted in the commercial product Integra (Integra Lifesciences, Princeton, NJ); Howard Green, who developed a keratinocyte cell sheet later marketed as Epicel (Cambridge, MA); and Eugene Bell, who created a bilayered construct that was later marketed as Apligraf (Basel, Switzerland).[3,4,41] John Burke, a burn surgeon in Boston, began working on skin replacements in the 1960s and had treated 10 patients with their dermal replacement by 1981.[3] Integra has been a successful dermal replacement that is still in use. Epicel is available as a humanitarian device indicated for autografting burns that are greater than 30% of total body surface area. Apligraf is primarily used to heal chronic venous and diabetic ulcers. However, these three products—Apligraf in particular because it consists of a scaffold with seeded cells—represent the first tissue-engineered solutions to reach patients. More recently, a cell therapy method of covering burns with an autologous epithelial suspension was developed by Fiona Wood.[42–44] This technology has been approved for use and is marketed as Recell (Avita Medical, Valencia, CA). Recell has several FDA-approved indications and is becoming widely adopted in the burn surgery community.

The first organ that went from bench to bedside as a permanent implant was the tissue-engineered bladder. Other tissues have since followed, including urethras and vaginas. The work on

bladders began in the early 1990s. The engineered bladders were first implanted into patients with spina bifida needing augmentation cystoplasty in 1999, and the initial results showed a follow-up of over 5 years.[45,46] The approach used involved taking autologous cells from a biopsy, expanding them, seeding them onto a biodegradable scaffold that was then preconditioned in a bioreactor, and finally, implanting the construct back into the patient.[40,46] The pediatric spina bifida patients showed normal bladder pressures.[40,46] Similarly, tissue-engineered urethras were implanted in five pediatric patients with long-segment urethral strictures. Biodegradable 5-cm tubularized scaffolds were seeded with the patient's own cells and showed normal flow rate, caliber, and architecture at 6 years of follow-up.[47]

Tissue-engineered vaginal organs have also been implanted.[48] The same approach was performed in four young females aged 13 to 18 years with vaginal agenesis, which consisted of taking autologous cells from a vulvar biopsy, expanding and seeding those cells onto a biodegradable scaffold, and implanting the constructs into the patients.[48] At 8 years of follow-up, the engineered vaginas showed normal structure and function.[48]

Tissue-engineered vascular grafts (TEVGs) have had success in clinical translation predominantly in congenital heart disease and end-stage renal disease, where they have been used as grafts for total cavopulmonary connection as part of a Glenn procedure and hemodialysis access, respectively.[49–54] The first case of TEVG in humans was to replace a thrombosed pulmonary artery in a patient with congenital cardiac disease, but subsequent implantations (in 25 patients) were primarily used for total cavopulmonary connection. These grafts have performed well, with no mortalities, graft rupture, graft infection, or ectopic calcification with a mean follow-up of 5.5 years.[49–52] One patient developed a thrombosis that was treated with anticoagulants, and four patients developed stenoses that were successfully treated with percutaneous angioplasty.[50] TEVGs have also been used for hemodialysis access in the form of scaffold-free cell sheets and as allogeneic ECM grafts generated from fibroblasts, with moderate success in phase I and II trials, although this method has not been approved in the United States.[53,54]

The alimentary tract and airways have been more challenging to translate to patients; however, there have been some case reports with the esophagus.[55] Although the alimentary tract is a hollow organ, it is complex. Recently, the first tissue-engineered esophageal replacement consisting of an adipose-derived MSC-seeded polyurethane esophageal implant (named *Cellspan esophageal*

implant [CEI]) was used in a patient who needed a long-segment esophageal resection for cancer.[55] A phase I clinical trial is now underway for CEI in the United States. To date, although there have been numerous approaches and attempts, regenerating small bowel for short bowel syndrome or functional colon for Hirschsprung disease has not moved beyond preclinical studies.[56–60] Significant progress has been made in the past 20 years, but there is still much work to be done before these organs will be available for patients.[56–60]

Solid organs are more difficult to engineer than hollow organs, and there has been less success with these organs so far. Because of the significant disease burden of kidney disease and the short supply of donor kidneys, tissue engineering and regeneration of kidney tissue have been an intense area of focus for the field, but to date, none of these approaches has reached the level of significant clinical translation.[61] One clinical trial attempted to use MSCs to reduce acute kidney injury (AKI) after cardiac surgery but found no difference between experimental and control groups, and the trial was stopped because of futility.[62] A second trial is underway that aims to use MSCs in a hemofiltration device (i.e., in the hollow fibers of the dialysis filter so that they are not injected into patients but their secreted factors will still reach the patient on dialysis) to provide immune modulatory effects and reduce damage to the kidneys and other organs.[63] This phase I trial will initially primarily evaluate the safety of such an approach. The use of hydrogels has garnered some attention as a delivery vehicle for MSCs and endothelial progenitors to the kidney to promote regeneration, but to date, this and other approaches using MSCs have failed to result in any clinically significant improvement in kidney function.[64] Another approach uses primary kidney cells that are isolated from the same patient, expanded, and inserted back with a collagen hydrogel. This technology has been successful in stabilizing renal function in human trials and is now in FDA phase III trials.[65,66] For an in-depth discussion of the state of the art in kidney regeneration, the reader is referred to the excellent review by Yang et al.[61]

Liver failure and the lack of available donor livers for transplant have also resulted in significant research in engineering and regenerating functional liver tissue.[40,67–69] Unfortunately, these efforts have not resulted in an engineered liver that is ready for transplant. Through a better understanding of the cell biology of hepatocytes and with the introduction of 3D cultures with organoids, there have been trials of extracorporeal liver-assist devices—like dialysis for the liver.[67] These devices often use cultured hepatocytes, often from a porcine source, to serve as the functional liver for a patient in liver failure. A recent meta-analysis of these devices and trials, however, showed no clear benefit in humans, with some benefit seen in preclinical models.[67] The authors of this study concluded that because several of the human trials were quite old, new trials might demonstrate a benefit, given improvements in cell culture since that time.[67] Others have attempted to use liver-derived MSCs to improve liver function in a failing liver, and a phase I/IIa European clinical trial is underway to test safety.[69] For more information regarding approaches to liver regeneration and tissue engineering, the reader is referred to the excellent review by Heydari et al.[68]

As has been alluded to in several earlier sections, MSCs have been used extensively to attempt to regenerate, tissue engineer, or immune modulate a chronic inflammatory response in many organs in the body. These approaches have included autologous and allogeneic-derived MSCs from numerous tissues (adipose, bone marrow, hematopoietic, etc.). MSCs have been seeded on scaffolds, injected intravenously, or injected into the body compartment or organ of interest.[11,70] These approaches have been used in many clinical trials treating a range of diseases, including amyotrophic lateral sclerosis, spinal cord injury, Parkinson disease, stroke, primary biliary cirrhosis, liver failure, renal failure, myocardial infarction/ischemic heart disease, heart failure, osteoarthritis, fractures, wound healing, diabetic foot ulcers, uterine injury, and vocal fold injury, with various levels of success.[70] The interested reader is directed to a recent review by Margiana et al. for further information.[70]

CHALLENGES IN REGENERATIVE MEDICINE

Despite the incredible advances, successes, and excitement around the field of regenerative medicine, many challenges still exist. Chief among the challenges is the problem of vascularization. If tissue-engineered constructs must rely solely on diffusion for nutrients and oxygen, it would be difficult to achieve any meaningful constructs larger than 0.5 mm^3 because of diffusion limits.[71] Constructs larger than this can be fabricated because the scaffolds used are generally porous, and the construct is typically not a dense structure initially. However, if clinically relevant tissues are to be fabricated in vitro, this limitation must be overcome. Many strategies have been employed, including using angiogenic factors to encourage vascularization after implantation, implanting constructs into the subcutaneous space or omentum to encourage vascularization, and more recently, engineering capillary conduits within the tissues using advanced fabrication techniques such as bioprinting.[71] The issue is so important that the National Aeronautics and Space Administration (NASA) released a vascular tissue engineering challenge to try to push the science forward.[72,73] First- and second-place winners for this challenge both used bioprinting to create a vascularized construct able to support and perfuse human liver cells to keep them alive for 30 days.[72,73] For more details on strategies to engineer vasculature in tissue-engineered constructs, the reader is referred to Yang et al.[71]

Aside from vascularization, the most important set of challenges that regenerative medicine will face are those involved in scaling up and manufacturing these technologies in an affordable and consistent way. In addition, the appropriate standards and regulatory approval pathways need to be developed.[74] For an excellent overview of these challenges, the reader is referred to Chapter 78 in *Principles of Regenerative Medicine,* titled "Regenerative Medicine Manufacturing – Challenges and Opportunities."[74]

Because regenerative medicine technologies frequently involve materials/devices, cells, and growth factors, they create a regulatory conundrum for the FDA because these treatments are not pharmaceuticals, devices, or biologics. Regenerative medicine suffers from difficulty in scaling up cell expansion, lack of automated monitoring and biosensors to monitor the progress of cell expansion and cell phenotypes, high costs, lack of sufficient quality control, lack of automation, lack of closed and modular systems, and lack of standards.[74] These areas will need significant investment to bring regenerative technologies to patients. Table 50.2 lists needed advances in manufacturing to bring the age of regenerative medicine to bear.

TABLE 50.2 **Areas of Needed Improvement for Regenerative Medicine Manufacturing**

FUTURE SYSTEM AREAS	SYSTEM ATTRIBUTES
Fully integrated/modular/dosed/sterile/automated manufacturing systems	• Closed, integrated purification, formulation, and vial fill
	• Seamless transition from media to bioreactor/cell culture vessel
	• Cell concentration standard method to maintain viability/potency
	• Customizable modules for expansion and cell retrieval
	• Automated cell handling in a fully controlled aseptic environment; scale-up for mass production
	• Passaging and layering multiple types of cells in a dosed system
	• Automatic monitoring of glucose utilization/lactose production to adjust nutrient supply for continuous feed
	• Off-the-shelf closed systems that can be easily upscaled
Xeno-free defined media systems	• Synthetic serum for human immune cells and mesenchymal stem cells first; following its success, it can be extended to other tissue sources in the human body
	• Universal "basal" media
	• Synthetic, defined serum substitute "panel"
Supply chain and logistic systems	• Platform technologies for shipping human stem cells and mesenchymal stem cells should be initially tested
	• Further development of formulations and methods for extending liquid storage stability
	• Further development and optimization of formulations and methods for freeze drying
Biosensing systems	• Three-dimensional printer for engineered tissues
	• Microfabrication of biosensors
	• Better oxygen- and glucose-monitoring sensors
	• Improved material for adherent cells to maximize cell seeding and harvesting
Nondestructive quality control systems	• One area is lactate and ammonia management
	• In-line measurement of cell density
	• Real-time cell "state"/phenotype monitoring
	• Data capture and mining/correlation
	• Microscope with software for recognizing and quantifying cellular structures
	• Disposable sensors or built-in sensors for growth factor levels in addition to pH, osmolarity, O_2, and CO_2; glucose, ammonia, and K^+ would be great as well
	• There will not be a path to a universal solution—too divergent; pick either most universal quality control specification/parameter (most therapy agnostic) or highest-impact upcoming therapy—propose and prototype a solution

Continued

TABLE 50.2 **Areas of Needed Improvement for Regenerative Medicine Manufacturing—cont'd**

FUTURE SYSTEM AREAS	SYSTEM ATTRIBUTES
Automated and dosed patient-specific systems	• Integrated, standardized disposables for product types
	• Processes that are patient specific and would involve modeling the patient's anatomy
	• Easily adaptable semiuniversal automated system
	• Semiuniversal disposables
	• Automated injector with detailed process control
	• Novel single-use sensors/sensing approaches for noninvasive monitoring/control of process parameters and detection of microbial contamination
	• Disposable single-use bioreactors that will support all steps, from seeding through harvest
	• Instrumentation that can provide CO_2 and temperature control without traditional incubators
Cell and tissue expansion systems	• Determine if same system could be scaled to fit both small- and large-scale needs
	• In-line cell "state"/phenotype monitoring
	• Scalable bioreactor technology
	• Novel single-use format for high-density cell culture (adaptable adherent or suspension, or tissue constructs)
	• Design for scale-out strategy for autologous therapies

CONCLUSION

Regenerative medicine is an exciting and rapidly advancing field that will ultimately revolutionize surgery and medicine. Significant advances have been made in the past 20 years, but there is still a long way to go. Numerous regenerative medicine technologies have reached patients, but the lofty goal of having off-the-shelf organs for transplant and regenerative solutions for all chronic diseases is still a long way off. Surgeons have been involved in tissue engineering and regenerative medicine from its inception, and the role of the surgeon in the field remains critical.

Rescue Liver Transplantation

INTRODUCTION

With both short- and long-term survival rates improving after solid organ transplantation, a growing number of recipients need nontransplantation-related medical care, including elective or emergency surgery. Perioperative and intraoperative management principles are similar for transplant and nontransplant patients; however, there are a few key differences. This chapter discusses potential preoperative, intraoperative, and postoperative issues related to nontransplant surgery in transplant patients. It also highlights the principles of surgery in patients with portal hypertension.

OPERATING ON TRANSPLANT PATIENTS

Preoperative Risk Stratification

To develop an initial estimate of perioperative risk, clinicians must integrate information from patient history, physical examination, and laboratory tests. Significant coronary artery disease in transplant recipients undergoing noncardiac surgery is a common finding and therefore should be a preoperative consideration. Several clinical and surgical determinants can be used to stratify the cardiac risk. Patients with cardiac disease undergoing noncardiac surgery must be assessed for their clinical risk profile in relation to the surgery to be performed and its associated risks.[1]

Although successful kidney transplantation decreases the overall cardiovascular risk in patients with end-stage renal disease (ESRD), cardiovascular disease is more prevalent in kidney transplant recipients than in the general population and remains the most common cause of death in kidney transplant patients. In addition, preexisting coronary artery disease progression can occur in posttransplant patients, largely because of immunosuppression contributing to de novo hyperlipidemia, hypertension, and diabetes. Because long-term studies on cardiac outcomes after nontransplant surgery in kidney transplant recipients are lacking, there are no specific recommendations for cardiovascular evaluation in transplant recipients. For previous kidney transplant patients undergoing nontransplant surgery, the American College of Cardiology/American Heart Association (ACC/AHA) guidelines for perioperative cardiovascular evaluation should be used to guide preoperative cardiovascular testing.[2]

Glucocorticoids

In the past, patients receiving azathioprine-based immunosuppression regimens frequently received chronic glucocorticoids, which caused characteristic side effects in many recipients. High perioperative doses of glucocorticoids are required in these patients because of adrenal suppression caused by high maintenance doses of steroids. In the era of more potent maintenance immunosuppressive agents such as tacrolimus, mycophenolate mofetil, and sirolimus, maintenance glucocorticoids are either reduced or avoided. As a result, adrenal suppression has become less problematic. It is generally unnecessary to administer high doses of glucocorticoids, and it may be contraindicated in some cases.[3]

The administration of high doses of glucocorticoids is not entirely benign and has occasionally been associated with gastritis, bleeding, induction of diabetes, and worsening of glycemic control. Although the cosyntropin test is often considered cumbersome, impractical, and somewhat unreliable, it can be used to help determine adrenal reserve in at-risk patients.

In those with adrenal insufficiency, glucocorticoids may be administered to patients starting at the time of anesthesia induction. Perioperative dosing of glucocorticoids depends on the surgical stress predicted to be caused by the procedure occurring. For example, in minor and moderately stressful procedures such as inguinal hernia repairs, colonoscopies, joint replacements, and colon resections, the patient's usual daily dose can be continued with 50 mg IV hydrocortisone given before incision followed by 25 mg IV every 8 hours for 24 hours before returning to the baseline dose. In major surgeries such as esophagectomy, hepaticojejunostomy, trauma, or major cardiac or vascular surgery, 100 mg IV hydrocortisone before incision followed by continuous IV infusion of hydrocortisone 200 mg for at least 24 hours or 50 mg every 8 hours for 24 hours followed by a taper can be given.[4] Perioperative infusion of glucocorticoids in this population may decrease the possibility of glucocorticoid deficiency as a cause of an adverse event such as hypotension, allowing the actual cause, like hemorrhage or volume depletion, to be identified and resolved.[5]

Another approach in managing patients on chronic glucocorticoids is to give half the baseline dose the day after surgery and resume the maintenance dose on the second postoperative day. Use of typical maintenance doses of glucocorticoids for this amount of time is unlikely to cause adverse effects. However, prolonged use of steroids can mask the signs and symptoms of infection and cause undesirable side effects, depicted in Fig. 51.1.

Mammalian Target of Rapamycin Inhibitors

The introduction of mammalian target of rapamycin (mTOR) inhibitors to the polydrug posttransplantation regimen led to an apparent increase in wound-related complications. This constitutes a serious clinical problem in the immediate posttransplantation period and in patients requiring further surgery while still receiving immunosuppressive drugs. In addition, studies have demonstrated that everolimus, administered as a single drug from the day of surgery onward, strongly interferes with restoring tissue strength in the intestinal tract and abdominal wall wounds.[6]

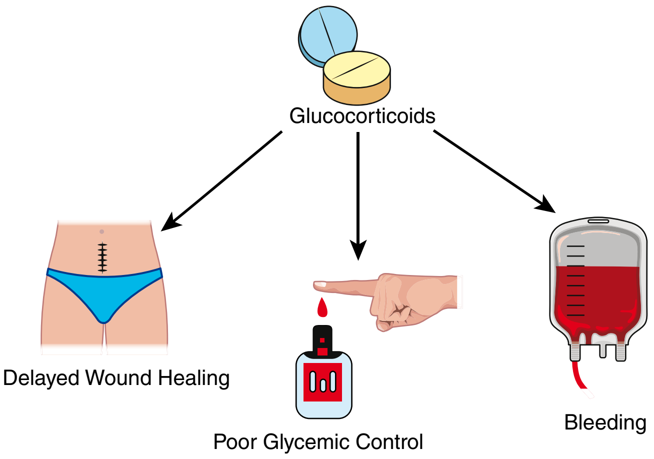

FIGURE 51.1 Potential complications from steroids.

Antibiotic Prophylaxis

Chronically immunosuppressed transplant patients may be at a higher risk of developing infectious complications after surgery. In most cases, routine antibiotic prophylaxis with a first-generation cephalosporin is sufficient.[7] In patients on cyclosporine or tacrolimus, erythromycin and clarithromycin must be avoided because they antagonize CYP 3A4 enzymes. However, it is important to note that azithromycin, like other macrolides, does not significantly affect cyclosporine or tacrolimus levels. Ciprofloxacin and clindamycin are safe alternatives that do not significantly affect the cyclosporine or tacrolimus levels.[8]

Surgical Outcomes

A recent study found that the incidence of emergency general surgery is significantly higher in transplant patients even after stratification by comorbidity burden.[7] In general, the published data suggest more complications in transplant patients undergoing nontransplant surgery than in nontransplant patients. For example, in patients undergoing cholecystectomy, mortality, morbidity, and length of stay were longer for kidney transplant recipients compared with nontransplant patients.[9] Similarly, in patients undergoing colorectal resections, in-hospital mortality was higher for kidney transplant recipients than nontransplant patients, as were overall complications. In addition, the length of stay was significantly longer and the cost was significantly greater in kidney transplant recipients than in nontransplant patients.[10–12] Similarly, studies have found that immunosuppressed patients experienced significantly higher rates of postoperative mortality after emergency surgery than immunocompetent patients undergoing surgery for diverticular disease.[13]

Wound Healing

Patients with chronic immunosuppression, even those receiving low doses of glucocorticoids, may have delayed wound healing after surgery.[14] Some immunosuppressive agents may exacerbate wound-healing complications during the immediate postoperative period.[14] Sirolimus is one example of an immunosuppressant that can lead to a higher incidence of adverse outcomes, such as wound complications. In one study, the incidence of allograft wound complications in the sirolimus group was significantly higher (47% vs. 8%) than the transplant recipients receiving tacrolimus.[15] There have also been reports of perigraft fluid collections, superficial wound infections, and incisional hernias associated with the use of sirolimus.[15,16]

Specific Surgical Problems

Transplant recipients have been shown to more commonly experience acute conditions requiring general emergency surgery, demonstrating a 3.6-fold higher incidence than their age-matched counterparts.[17] Surgical complications in transplant patients may be masked by chronic immunosuppressive therapy, which can lead to significant morbidity and mortality. A review of operative reports and common surgical incisions made for liver and kidney transplants is essential for operative planning (Fig. 51.2).

Acute appendicitis can be particularly difficult to diagnose in kidney or pancreatic transplant patients with transplanted organs in the right lower quadrant. The symptoms and signs are often uncharacteristic because the transplanted organ displaces the appendix superiorly (Fig. 51.3). The appendix is often perforated by the time a diagnosis is made, as these patients may either be asymptomatic or show no signs of a perforated viscus in terms of physical examination or laboratory data because of being

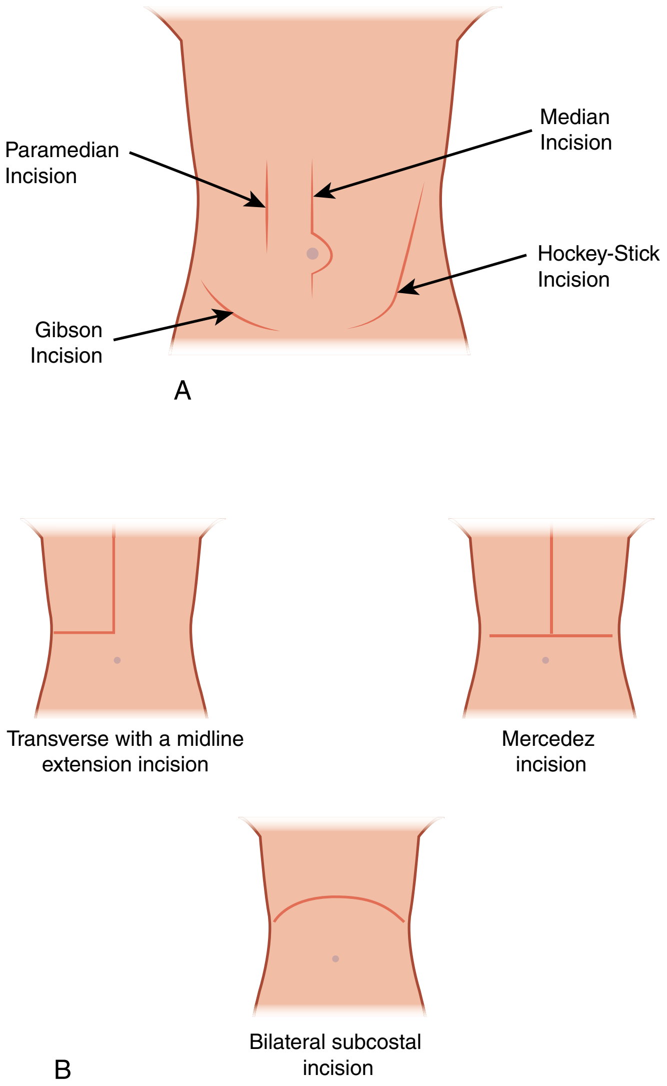

FIGURE 51.2 (A) Common incisions for kidney transplant. (B) Common incisions for liver transplant.

immunocompromised. Additionally, laparoscopic port placement may be challenging because of transplanted organ placement. For minimally invasive surgeries of the pelvis, such as colorectal or gynecologic procedures (e.g., colectomy or hysterectomy), attention should be paid to port placement. The transplanted kidney is placed retroperitoneally and should not be of concern to the operative surgeon. Upper gastrointestinal or hepatobiliary surgery, such as cholecystectomy, after a kidney transplant should be performed in the usual fashion, and port placement should not be affected.

Prior liver transplant and the formation of adhesions in the upper abdomen frequently lead to increased complexity in upper gastrointestinal surgery, such as sleeve gastrectomy. However, adhesions in transplant patients are typically less dense because of chronic steroid use and immunosuppression. Biliary anatomy after a liver transplant must also be considered, and operative reports from the transplant should be obtained preoperatively for any surgery involving the gastrointestinal tract, such as Roux-en-Y gastric bypass or total abdominal colectomy. For example, if a Roux-en-Y hepaticojejunostomy was performed during the liver transplant, the surgeon should be aware before entry into the abdomen, if possible, so appropriate surgical planning can occur.

Other common surgical procedures performed after liver transplant are hernia repairs, especially umbilical and inguinal hernia repairs. Patients with ascites may develop incarceration of their umbilical or inguinal hernia as the ascites resolves after liver transplantation. Emergency repair of strangulated hernias should be performed. In cases of symptomatic or incarcerated hernias that do not require emergent intervention, it is ideal to wait 6 months to 1 year before interventions to allow patients to be weaned off steroids and most prophylactic medications. The use of mTOR inhibitors in transplantation surgery has been associated with increased wound complications and hernias. Animal studies have previously reported a negative effect of everolimus on anastomotic strength in rat intestines 7 days postoperatively.[18] This loss of strength was also accompanied by a decrease in the hydroxyproline content after 7 days, and the negative effect of everolimus on wound repair persisted for at least 4 weeks after the operation in this rodent model. Therefore, having the patient off mTOR inhibitors weeks before a planned surgery is ideal to help avoid unnecessary healing complications. Though no clinical studies describing differences in outcomes between open and laparoscopic hernia repair exist, the benefits of laparoscopic surgery seen in the general patient population, such as reduced postoperative pain, faster recovery, and fewer wound complications, remain true in transplant patients.

Dialysis access creation is occasionally needed after liver transplantation. The incidence of ESRD after nonrenal solid organ transplantation is increasing and is associated with a poor prognosis. The etiology of ESRD is multifactorial but is most commonly the result of calcineurin inhibitor nephrotoxicity. The impact of the dialysis modality on the survival of these patients remains unclear. An arteriovenous (AV) fistula is a better option than a peritoneal dialysis catheter, which is usually avoided in patients with recent liver transplants, ascites, or a current abdominal hernia.[19] Other factors to consider include adhesions after surgery, synthetic vascular grafts used during liver transplant, and concern for secondary peritonitis.[20] Peritoneal dialysis catheter placement should be avoided in patients being evaluated for liver transplantation because of several factors, including coagulopathy and thrombocytopenia, presence of abdominal wall varices, ascites, and inability to use it effectively after liver transplantation.

Repairing an abdominal aortic aneurysm (AAA) requires cross-clamping of the abdominal aorta to allow anastomosis between the distal and proximal aortas. In addition, a temporary bypass from the ipsilateral axillary artery to the femoral artery may be needed to ensure continuous arterial blood supply to the transplanted kidney. In this way, the aneurysm can be repaired precisely while reducing the risk of allograft thrombosis.

Tertiary hyperparathyroidism occurs in up to 40% of patients undergoing kidney transplants. Persistent elevation of serum parathyroid hormone can increase the risk for long-term bone loss and decrease allograft and patient survival after transplant. Parathyroidectomy has high cure rates and reduced graft failure rates.[21] However, recent data suggest that surgery may be underused compared with medical management in these patients. Therefore, these patients should be referred to endocrinology for hypercalcemia workup.

OPERATING ON PATIENTS WITH PORTAL HYPERTENSION

Predicting Surgical Risk in a Patient With Cirrhosis

Surgical procedures that may be required in patients with cirrhosis can be categorized as procedures that improve a patient's quality of life, such as symptomatic hernia repairs, or as lifesaving procedures, such as cardiovascular surgery, cancer surgery, or emergency interventions. From simple procedures like umbilical hernia repairs (Fig. 51.4) to more complex liver resections for malignancy (Fig. 51.5), any surgery in a patient with cirrhosis poses unique challenges.

The first challenge for the care team is to assess the surgical risks before deciding whether the procedure can be carried out safely. Deciding whether a procedure should be performed at presentation, delayed until the patient has undergone liver transplantation, or avoided entirely depends on many factors including clinical status, decompensations, and likelihood of transplant candidacy. Surgical and consultative teams during decision-making must also consider the idea of futility. It is advisable to avoid the procedure regardless of the degree of liver disease if the surgical risks outweigh the chances of a good outcome. In a study by Teh et al., cirrhotic patients classified as American Society of Anesthesiologists (ASA) class V had a median survival rate of 2 days, a 90% mortality rate at 14 days, and a 100% mortality rate at 90 days. Postoperative mortality and complications increase with hepatic dysfunction, increased comorbidities, type of surgery, and decreased expertise of the management team.[22] The severity of liver disease appears to have the greatest impact on mortality risk. Another study found that cirrhotic patients undergoing coronary artery bypass graft had an eightfold increased risk of death compared with those without cirrhosis.[23] They also

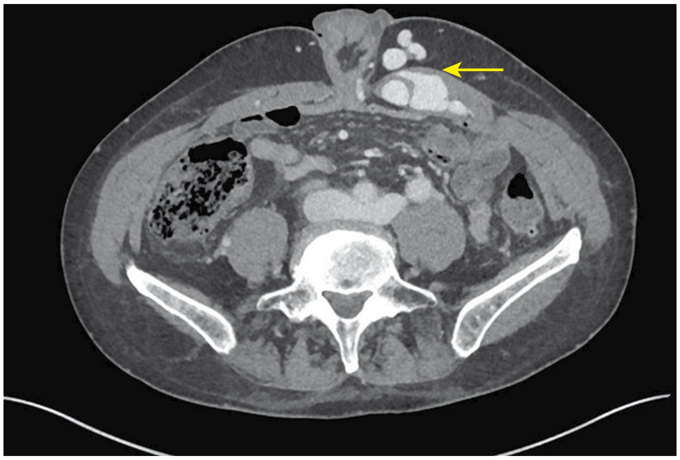

FIGURE 51.4 Umbilical hernia in a patient with portal hypertension and large varices *(arrow)* seen.

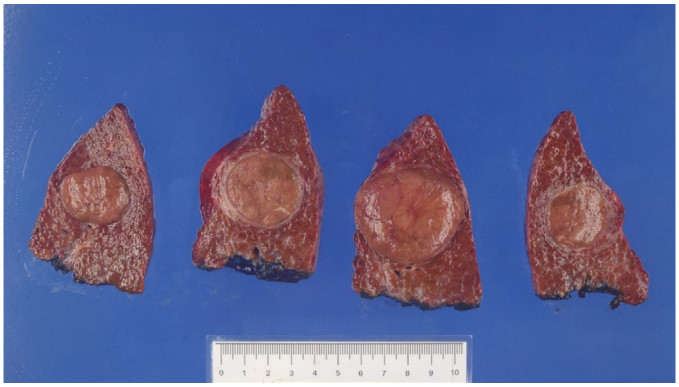

FIGURE 51.5 Malignancy in patients with cirrhosis.

found higher mortality rates in patients undergoing cholecystectomy, colectomy, or AAA repair.[23] Liver disease severity has traditionally been measured using the Child-Turcotte-Pugh (CTP) score (Child-Pugh class) and Model for End-Stage Liver Disease (MELD) score.

Child-Turcotte-Pugh Score

In patients with cirrhosis, the CTP score has been traditionally used to assess the severity of liver dysfunction and portal hypertension. Table 51.1 highlights the classification of CTP and its scoring system. Before the use of MELD scores, studies noted a good correlation between surgical mortality and Child-Pugh class when evaluated in combination with other variables.

Generally, patients with class A cirrhosis may be treated with surgery when there is no thrombocytopenia or clinically significant portal hypertension. Elective surgery is generally not considered for patients with class B or C cirrhosis.

However, recent analyses show less correlation between the Child-Pugh class and surgical outcomes, likely because of the low number of patients with Child-Pugh class C cirrhosis included in the modern series. In addition, patients with decompensated cirrhosis are more likely to avoid or not be offered surgery. Ascites, however, often correlates more reliably with poor surgical outcomes.

CTP scores have largely been supplanted by the MELD score for surgical risk stratification because of the subjective nature of assessing the severity of ascites and encephalopathy, which encapsulates the objective liver function–dependent components of the CTP score that are predictive of outcomes. In patients with severe portal hypertension but preserved hepatic synthetic function, the MELD score may be less effective, and the CTP score may be more useful.

Model for End-Stage Liver Disease Score

The MELD score was originally developed to predict mortality after transjugular intrahepatic portosystemic shunt (TIPS) placement. The MELD score can be calculated using the international normalized ratio (INR), serum creatinine level, and serum bilirubin level, with sodium also being considered in the more recent MELD-Na score. It has been shown that patients with preoperative MELD scores <16 have lower postoperative mortality rates than those with higher scores. Table 51.2 compares and contrasts the components of MELD and CTP scores.

An increase in the MELD score has been found to be positively correlated with postoperative mortality. Studies have shown that the most important predictors of mortality after surgery in patients with cirrhosis include the severity of cirrhosis as reflected by the MELD score, ASA classification and patient comorbidities, and age.[22] Others have shown that mortality is increased after surgery in the cirrhotic population for up to 90 days postoperatively after major surgery, independent of the type of surgery performed.[23] Not only has mortality been shown to increase in patients with cirrhosis after surgery, but studies have also demonstrated an increase in hospital cost and length of stay, even for those without portal hypertension.[24]

TABLE 51.1 Child-Pugh Score

COMPONENT	1	2	3
Bilirubin	≤2 mg/mL	2–3 mg/mL	≥3 mg/mL
INR	≤1.6	1.7–2.2	≥2.3
Serum albumin	≥3.5 mg/mL	2.8–3.5 mg/mL	≤2.7 mg/mL
Ascites	None	Slight	Moderate
Hepatic encephalopathy	None	Grade 1 or 2	Grade 3 or 4
Class	**A = 5–6**	**B = 7–9**	**C = 10–15**

INR, International normalized ratio.

TABLE 51.2 Components of MELD and CTP Scores

Bilirubin	Bilirubin
INR	INR
Creatinine	Serum albumin
Sodium (only included in MELD-Na)	Ascites
	Hepatic encephalopathy

CTP, Child-Turcotte-Pugh; *INR,* international normalized ratio; *MELD,* Model for End-Stage Liver Disease.

American Society of Anesthesiologists Classification

Since the early 1940s, the ASA physical classification system has been used as a measure of surgical anesthesia risk. ASA classification ranges from I to VI, with increasing classes representing increasing levels of comorbidities and illness, represented by Table 51.3. Although ASA score is correlated with surgical outcomes in some circumstances, it is generally regarded as a measure of disease severity or comorbidity rather than a direct predictor of outcomes, particularly in patients with cirrhosis. In addition, the classification system suffers from poor interobserver variability and is somewhat subjective. Moreover, there is no category for moderate diseases, only mild ones. Despite these weaknesses, ASA classification is still widely used for risk stratification before invasive procedures in the general surgical population and has been shown to correlate with increased mortality risk in patients with cirrhosis.[22–25]

Preoperative and Perioperative Evaluation and Management of the Patient With Cirrhosis

Patients with decompensated cirrhosis may be at high risk of complications from surgical procedures that are generally considered safe in the noncirrhotic population. A multidisciplinary medical and surgical team with extensive experience is essential for success. In this population, an informed decision about surgical procedures requires earnest, data-driven discussions with the patient and surgical teams.[23] The discussion should begin as early

TABLE 51.3 ASA Classification

ASA CLASS	PATIENT DESCRIPTION
Class I	Normal healthy patient
Class II	Patient with mild systemic disease
Class III	Patient with severe systemic disease
Class IV	Patient with severe systemic disease that is a constant threat to life
Class V	Moribund patient who is unlikely to survive without intervention
Class VI	Patient who has been declared brain-dead

ASA, American Society of Anesthesiologists.

as possible in the process. For example, in patients undergoing elective or semielective procedures, ascites should be controlled, variceal bleeding should be reduced, acute hepatic encephalopathy should be treated preoperatively, and medical treatment should be continued to prevent recurrence. In addition, patients with cirrhosis are likely to have nonhepatic risk factors for surgical complications because of aging and the increasing prevalence of obesity, nonalcoholic steatohepatitis (NASH), and diabetes mellitus.[24]

There is evidence that class III obesity and cardiopulmonary disease are risk factors for morbidity and mortality regardless of liver disease severity. Most risk stratification scores do not include age; however, age is known to be an independent risk factor for medical and surgical complications. CTP and MELD scores predict surgical outcomes only in patients who are otherwise satisfactory candidates for surgery and have no significant comorbidities.[26] These complex patients often require cardiology and pulmonology consultations.

It is generally recommended that patients with cirrhosis avoid elective operations until liver disease can be optimally controlled. It is well-documented that patients with postoperative compensated cirrhosis may still be at risk for progression to decompensated cirrhosis. For chronic viral and autoimmune hepatitis, antiviral and immunosuppressive therapy must be adhered to strictly to prevent viral resistance and relapses.[27] To avoid treatment interruption, elective or semielective surgery may be delayed until therapy is completed. Patients with autoimmune hepatitis who cannot take oral medications such as corticosteroids may require alternative routes of drug administration.

For patients undergoing liver surgery, portal hypertension should be assessed. A measure such as the hepatic venous pressure gradient or the presence of gastroesophageal varices should be used instead of surrogate markers such as splenomegaly or thrombocytopenia.[28] Compared with patients without portal hypertension, patients with clinically significant portal hypertension have a double mortality rate and a threefold complication rate.[29]

Ascites

Practice guidelines recommend aggressive management of ascites before surgical procedures if possible. Ascites can restrict pulmonary function and delay recovery of lung function after surgery. A patient with ascites may also experience pulmonary aspiration during induction. Preoperatively, large-volume abdominal paracenteses should be performed in patients with symptomatic ascites, followed by intravenous administration of albumin 6 to 8 g/L of ascitic fluid removed.[30] According to practice guidelines, oral antibiotic prophylaxis can be started in patients with concern for development of spontaneous bacterial peritonitis or with low ascitic total protein concentrations once oral medications are tolerated. If a patient cannot take oral medications, third-generation cephalosporins such as ceftriaxone can be administered intravenously at 1 g every 24 hours until oral antimicrobials are tolerated. Patients with moderate to large pleural effusions that compromise respiratory function should be evaluated for preoperative thoracentesis. Blood products and intravenous fluids should be limited perioperatively to minimize the development of extracellular volume and ascites.[31] Surgical drains are usually avoided in the postoperative period because of infection concerns. These patients, however, may require serial paracentesis in the postoperative period.

TIPS placement before surgery has only been investigated in a few case reports and uncontrolled case series to reduce the risk of collateral vessels and intraabdominal variceal bleeding during surgery.[32] Although TIPS placement has been shown to reduce intraoperative blood transfusions, the available studies have been uncontrolled, and the frequency of complications such as hepatic encephalopathy was not reported.[33] Alternatively, studies comparing patients who underwent TIPS placement before liver transplantation with those who had not undergone TIPS placement revealed no differences in the need for red blood cell or plasma transfusions.[34] Furthermore, TIPS placed in the right atrium, inferior vena cava, or mesenteric veins of a patient undergoing nontransplant surgery may adversely affect future liver transplantation. Thus, preemptive TIPS placement before surgery is not recommended as a routine practice because of its unproven efficacy, lack of published evidence, high complication rates, and significant additional costs.

Hemostasis and Coagulation

Based on preoperative platelet counts and INRs, protocolized transfusion strategies do not reduce intraoperative or postoperative bleeding.[35] Patients with cirrhosis do not always have an increased risk of severe bleeding based on laboratory values alone. Procoagulant factor deficits are offset by anticoagulant protein deficits synthesized by the liver, resulting in a state of "rebalancing." As liver disease progresses, protein C deficiency may progress to thrombophilia in some patients. Therefore, preoperative blood transfusions are not always required. INR does not predict bleeding complications in patients with cirrhosis, and "prophylactic" preoperative fresh frozen plasma transfusion is not recommended. Although thrombocytopenia is common in patients with cirrhosis, in vitro and retrospective cross-sectional studies have shown that platelet counts above 50,000/μL are adequate to allow clot formation in most patients with cirrhosis.[36] Therefore, increasing platelet count with prophylactic transfusions may not be beneficial and can cause problems such as volume overload, thrombosis, and transfusion-related complications. It has recently been discovered that thrombocytopenia caused by idiopathic thrombocytopenic purpura can be treated with thrombopoietin analogs (romiplostim) and receptor agonists (eltrombopag, avatrombopag, and lusutrombopag).[35] During interferon-based antiviral therapy, eltrombopag is also approved for use in patients with cirrhosis caused by chronic hepatitis C to increase platelet counts. Only avatrombopag and lusutrombopag have been approved for general thrombocytopenia related to liver disease. In patients with cirrhosis, avatrombopag and lusutrombopag were effective in raising platelet counts above 50,000/μL in phase III clinical trials when administered before invasive procedures compared with placebo.[37]

Although there is no clear guidance in the literature for using these agents preoperatively in patients with cirrhosis, it seems reasonable to use them when the platelet count is less than 50,000/μL when undergoing an elective procedure associated with high bleeding risk. It is important to pay special attention to the possibility of thrombotic events such as portal vein thrombosis and other deep vein thromboses. These agents are currently being studied in clinical settings.

Patients with cirrhosis may have quantitative or qualitative abnormalities in their coagulation profile.[38] Low fibrinogen levels are associated with a higher risk of bleeding, whereas levels above 100 mg/dL inhibit clot formation in patients with cirrhosis.[36] Cryoprecipitate transfusions are a low-volume replacement for fibrinogen that do not significantly increase plasma volume. Despite the lack of controlled trials examining the efficacy of fibrinogen transfusion in patients with cirrhosis, it seems physiologically reasonable to resupply fibrinogen levels with cryoprecipitate before high-risk surgery to ensure adequate clot formation.

Viscoelastic testing (thromboelastography and rotational thromboelastometry) during intraoperative transfusions in large centers has been shown to reduce the need for red blood cell and plasma transfusions in surgical patients with cirrhosis. Therefore, viscoelastic testing should be considered before and during surgical procedures in patients with cirrhosis as a guide for a rational transfusion strategy.[39]

Assessing preoperative imaging to locate varices is an important aspect of preparing for these cases. Fig. 51.6 shows the common locations of these varices.

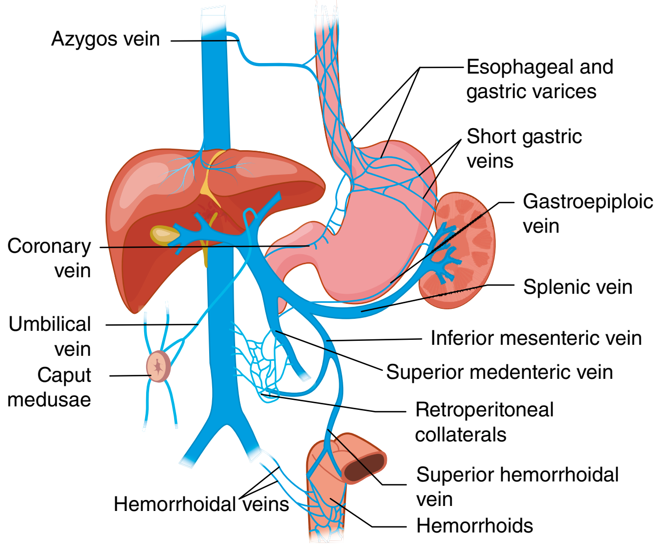

FIGURE 51.6 Sites of varices to be aware of anatomically when operating on patients with cirrhosis. (From Rikkers LF. Portal hypertension. In: Miller TA, ed. *Physiologic Basis of Modern Surgical Care*. St Louis: Mosby; 1988:417-428.)

Pain Control

Drug-related toxicity is particularly high in patients with cirrhosis because of altered drug metabolism and elimination. Therefore, opioid dosages and dosing intervals should generally be lower than the standard. Although randomized controlled trials have not been conducted in patients with cirrhosis, hydromorphone and transdermal fentanyl may be the preferred agents.[40] Tramadol, which has favorable hepatic metabolism, is also commonly used in this population.

As benzodiazepines are eliminated primarily through protein binding and hepatic metabolism, it is best to use short-acting benzodiazepines, such as midazolam. Although there is a misconception that acetaminophen, even in small doses, is contraindicated in patients with cirrhosis, a daily maximum of 2 g/day is generally acceptable. Patients with cirrhosis should avoid the routine administration of nonsteroidal antiinflammatory drugs (NSAIDs) because they can impair renal blood flow. Additionally, oral combination products containing acetaminophen or NSAIDs, especially when combined with opioids, should not be administered because they can cause accidental toxicity or overdose if the patient is unaware that acetaminophen is a component of the product.[41]

For patients with cirrhosis, polyethylene glycol solution may be used daily to maintain bowel regularity and minimize hepatic encephalopathy flare-ups. In the absence of comparative trials, rifaximin may be preferred in patients with hepatic encephalopathy who undergo primary bowel surgery because it generally causes less bowel distention than lactulose.

Table 51.4 shows the optimization strategies for patients with cirrhosis.

Rescue Liver Transplantation

It is important to determine if a patient is likely to be a candidate for liver transplantation before undergoing a surgical procedure. Before proceeding with surgery, it is essential to clarify the

TABLE 51.4 Optimization Strategies in Patients With Cirrhosis

PREOPERATIVE CONCERNS	PATHOPHYSIOLOGIC CHANGES	POTENTIAL COMPLICATIONS	ASSESSMENT	PERIOPERATIVE OPTIMIZATION
Nutrition and metabolism	Protein calorie malnutrition Depletion of glycogen storage	Muscle wasting, impaired mobility, increased need for postoperative ventilation, impaired wound healing, sepsis, and delay in recovery	Serum albumin Anthropometric measurement	Diet with high carbohydrate, high lipid content, and low in amino acid Protein intake of 1.0–1.5 g/kg daily Monitoring for hypoglycemia and hyperglycemia Vitamin B_1 in alcoholics
Portal hypertension and ascites	Portal hypertension	Decreased quality of life, spontaneous bacterial peritonitis, increased risk of abdominal wound dehiscence, recurrence of abdominal wall hernia, and respiratory compromise	Clinical evaluation Ultrasonography	Salt and water restriction, diuretics Ascitic fluid analysis SBP treatment and prophylaxis Large-volume paracentesis for uncontrolled ascites with albumin TIPS for refractory ascites
Renal	Low renal blood flow and low glomerular filtration rate Raised aldosterone	Acute kidney injury Hepatorenal syndrome	Serum creatinine, GFR, and urine analysis	Fluid and electrolyte balance Avoid nephrotoxic drugs, including contrast agents Combination of albumin and terlipressin or octreotide with midodrine in HRS

TABLE 51.4 Optimization Strategies in Patients With Cirrhosis—cont'd

PREOPERATIVE CONCERNS	PATHOPHYSIOLOGIC CHANGES	POTENTIAL COMPLICATIONS	ASSESSMENT	PERIOPERATIVE OPTIMIZATION
Cerebral	Glial edema	Hepatic encephalopathy	Clinical assessment	Use of lactulose, metronidazole, and neomycin
	Increased permeability of blood-brain barrier		Serum ammonia level	Rifaximin and branched-chain amino acids
	Increased sensitivity to opioids			Treat infections, avoid diuretics, and constipation
				Correct electrolyte abnormalities
Pulmonary	Pleural effusion	Hypoxemia	Chest imaging	Optimize pulmonary functions
	Hepatopulmonary syndrome	Respiratory compromise	Bubble ECHO for HPS	Incentive spirometry
	portopulmonary hypertension		Pulmonary function tests	Intravenous prostacyclin in selective cases
Cardiac	Increased cardiac output, Systemic vasodilation	Cardiomyopathy	Dobutamine stress ECHO	Optimization of fluid status
				ACC and AHA guidelines for noncardiac surgery
				β-Blockers in perioperative period (need reference)
Electrolytes and metabolism	Hyponatremia (fluid overload)	Electrolyte disorders	Check serum electrolytes	Monitor and correct hyponatremia and hypokalemia
	Hypoglycemia (depletion of glycogen stores)			Blood sugar monitoring
Hematology	Thrombocytopenia, hypocoagulability, and hypercoagulability	Anemia, bleeding, thrombocytopenia	Complete blood count, coagulation profile, thromboelastography	Maintain Hb >10 g/dL
	Bone marrow suppression			INR correction with intravenous vitamin K, FFP, and cryoprecipitate
				May need DDAVP, recombinant factor VIIa, aprotinin, and tranexamic acid
				Prophylactic platelets transfusion for platelets <50,000

position of patients who are not potential candidates for liver transplantation to prevent the patient's family and medical team from revisiting this issue if the patient's condition deteriorates postoperatively. In addition, it is important to determine whether the patient is a candidate for liver transplantation and if the planned surgery can be postponed until the patient has undergone transplantation. Despite uncertainty about how long the patient will be on the liver transplant waiting list, elective procedures such as orthopedic procedures may be best deferred. When a procedure cannot be delayed because of its adverse impact on the patient's quality of life, it is best to complete the liver transplant evaluation before the anticipated surgery. Choosing whether to undergo a liver transplant is not easy and depends, in part, on how quickly a liver transplant evaluation can be completed if the patient deteriorates after surgery and how likely the patient is to undergo a liver transplant. A preoperative evaluation for liver transplantation is recommended if the postoperative mortality risk is >15% at 3 months using an appropriate risk calculator or if the MELD score is >15 (a score that predicts an increased mortality rate).[42,43]

Summary

INDICATIONS FOR KIDNEY TRANSPLANTATION

The United States has a heavy chronic kidney disease (CKD) burden, with one in seven adults, or 37 million Americans, carrying the diagnosis. CKD is more common in people aged 65 years or older (34%) than in people aged 45 to 64 years (12%) or 18 to 44 years (6%).[1] Numerous studies have shown that patients who progress to end-stage kidney disease (ESKD) have a survival advantage and improved quality of life if they undergo kidney transplantation compared with remaining on dialysis, establishing kidney transplantation as the gold standard for the treatment of ESKD.[1] Long-term survival for patients after kidney transplant is significantly better in comparison to patients who remain on the transplant waiting list, with a 50% lower 5-year mortality risk among transplant recipients compared with waiting-list candidates.[2] Importantly, the aging US population is projected to increase the CKD prevalence and risk for progression to ESKD and thus drive increased demand for kidney transplantation.

CKD can be caused by numerous disease processes, some of which are more common than others. Hypertension and diabetes are the most common etiologies, with a unique pathophysiologic basis for causing chronic kidney damage. Hyaline arteriosclerosis, seen in hypertensive kidney disease, results from recurring injury to endothelium. This leads to leaking of plasma proteins and platelets, causing a cascade of events resulting in medial and intimal thickening.[3] Diffuse thickening of basement membranes and mesangial sclerosis are the prominent morphologic features seen in kidneys of patients with diabetes, which leads to nephrotic syndrome.[3] At the macrovascular level, diabetes leads to atherosclerosis of renal arteries, leading to progressive ischemia, which leads to scarring and loss of kidney function. Autosomal dominant polycystic kidney disease (ADPKD) is another common etiology causing progressive CKD, accounting for about 10% of CKD burden in the United States. The underlying defect lies in *PKD1* or *PKD2* gene expression, which leads to development of cysts from nephrons and progressive loss of renal parenchyma.[4] Less common causes include systemic lupus erythematous, membranous nephropathy, minimal change disease, and membroproliferative glomerulonephritis (MPGN) type 1.

The most common indications for transplantation in the pediatric population are different as compared with adults because CKD is rare in children. For children below the age of 5, ESKD most commonly results from congenital anomalies of the kidney and urinary tract, such as renal aplasia, obstructive urologic malformations, and focal sclerosing glomerulosclerosis (FSGS). Reflux nephropathy, chronic glomerulonephritis, and polycystic and medullary cystic disease are even rarer causes of ESKD in children. An in-depth overview of indications seen in the pediatric population is beyond the scope of this chapter.

Patient Selection for Kidney Transplantation[5]

Across the United States, there are more than 250 transplant centers that perform kidney transplants. Every center has internal processes through which they evaluate patients to be considered for kidney transplantation. Existing guidelines encourage consideration of local factors when evaluating patients for kidney transplantation and emphasize the need to select patients for whom kidney transplantation will increase quality and/or quantity of life compared with dialysis. For example, it may not be suitable to have an 80-year-old undergo kidney transplantation and experience the potential diminished quality of life associated with immunosuppressive side effects if their life expectancy remains unchanged compared with remaining on dialysis.

Consideration for transplantation begins with referral from a general nephrologist. Ideally, candidates are referred for evaluation 6 to 12 months before anticipated dialysis initiation. This allows for possible preemptive transplantation, particularly when suitable living kidney donors are identified. Therefore, estimated glomerular filtration rate (eGFR) ≤30 mL/min/1.73 m^2 is the typical trigger most nephrologists use to initiate discussions with patients regarding referral for kidney transplantation. It is important to note, however, that disparities in access to preemptive referral and transplantation exist, particularly for ethnic minorities and those with poor social determinants of health.[6]

There are numerous medical conditions that may make a patient high risk or unsuitable for kidney transplantation. We can subdivide patient assessment for transplantation based on system:

- **Neurologic diseases:** Recovery from cerebrovascular accidents is variable. Some patients may never be candidates for transplantation after a stroke, depending on severity of residual neurologic deficits. Generally, a wait of 6 months is recommended after a stroke and 3 months after a transient ischemic attack (TIA). Those patients who have progressive central neurodegenerative disorder do not have improved quality of life or increased survival benefit after transplantation; hence, they are generally not considered for transplantation. Patients who have stable cognitive impairment but do not have an underlying neurodegenerative disorder are considered for transplantation if they have an appropriate social support structure or are able to demonstrate acceptable activities of daily living (ADLs). Candidates with ADPKD are at risk for intracerebral aneurysms. If there is a family history of subarachnoid hemorrhages or a personal history of unexplained headaches, they are usually screened with MRI of the head to rule out aneurysms before transplantation. Peripheral neuropathies are frequently encountered in ESKD patients, mostly as a result of a history of uncontrolled diabetes mellitus. Peripheral neuropathies do not exclude patients from kidney transplantation unless they are severely debilitated and are not expected to recover after a major operation because of the high risk of complications associated with immobilization in perioperative period.
- **Cardiovascular diseases:** Patients with ESKD need to be thoroughly investigated for possible underlying cardiovascular disease (CVD). Baseline workup includes an electrocardiogram (ECG) and echocardiogram (ECHO). Those who have good functional status and minimal risk factors for coronary artery disease (CAD) are initially screened with a nuclear medicine stress test. Some centers are more conservative with regard to using noninvasive cardiac stress tests, but based on local population characteristics, many centers routinely use stress tests as part of preoperative workup. If nuclear stress test is suggestive of underlying CAD, patients are referred to a cardiologist for further workup. High-risk patients with long-standing diabetes or a history of heavy smoking should be considered for left heart catheterization as part of initial workup. Those who have advanced triple-vessel disease or critical lesions are referred to cardiologists for further treatment before being considered. After cardiac stent placement, it is advisable to wait until the patient is off dual-antiplatelet therapy, typically a delay of 6 to 12 months, before wait-listing and/or transplanting the patient. If ECHO is suggestive of heart failure, patients are referred to a cardiologist for further evaluation. Having an ejection fraction of $<30\%$ is usually a contraindication for being considered for kidney transplant alone. Patients with severe uncorrectable pulmonary hypertension are also not candidates. Those patients with pulmonary artery pressures above 45 mm Hg are first evaluated by cardiology, but those with pressures above 60 mm Hg are not considered candidates for kidney transplantation alone. One needs to be aware of the reversible depressed ejection fraction that may be encountered in patients who have advanced CKD but have not initiated dialysis. Specifically, the reduced ejection fraction may simply reflect underlying volume overload, which can be corrected with dialysis initiation. Moreover, patients already on dialysis may also have reduced ejection fractions from volume overload secondary to inaccuracies in their dry weight, resulting in underdialysis of the patients. In both instances, optimization of volume control/status is initiated (e.g., dialysis initiation or more aggressive fluid removal), followed by repeat ECHO once euvolemia is achieved. Finally, patients with active symptoms concerning for CAD or valvular disease should be referred to a cardiologist for detailed workup and management before referral for kidney transplant evaluation.
- **Pulmonary diseases:** All patients should undergo x-ray of the chest as a minimum when undergoing evaluation for kidney transplant. Patients who are active smokers or have a heavy smoking history (≥30 pack-years) should undergo computed tomography (CT) scanning of the chest as well. Patients are encouraged and counseled regarding smoking cessation. Patients with irreversible severe obstructive or restrictive lung disease are not considered in isolation for kidney transplant and may be considered if they are candidates for lung transplantation.
- **Gastrointestinal diseases:** Patients should be evaluated with esophagoduodenoscopy (EGD) if they have long-standing history concerning for peptic ulcer disease. Any active inflammation/infection needs to be resolved before considering transplantation. Among labs done at the time of transplant evaluation are liver function tests, which necessitate further workup if abnormal. Patients with underlying cirrhosis need to be referred for simultaneous liver-kidney transplantation. In some rare cases, patients with early compensated cirrhosis may be able to undergo isolated kidney transplantation. Patients with underlying ulcerative colitis and Crohn's disease must have the disease under control before being considered. Colonoscopy is completed in all patients over the age of 45 for colorectal screening, and this is done earlier in patients with inflammatory bowel disease per disease-specific guidelines.
- **Hematologic diseases:** As the average age of the US population increases, a greater number of patients undergoing kidney transplant evaluation are found to have primary hematologic malignancies/disorders. Generally, patients with monoclonal gammopathy of undermined significance (MGUS) and smoldering multiple myeloma remain candidates for transplantation. Patients should, however, be counseled about the risk of disease progression before proceeding with transplantation. Cytopenia encountered in a routine laboratory workup should be carefully evaluated, and if the etiology is unclear, a referral to a hematologist should be made. If there is a history of unexplained blood clots, patients should be evaluated for thrombophilias, such as antiphospholipid antibodies. Anticoagulation preoperatively for hypercoagulable disorders is not contraindicated, but it is usual practice to discontinue novel anticoagulants (e.g., apixaban) and switch to warfarin while waiting for transplant. As previously discussed, patients on dual-antiplatelet therapy for cardiac stenting should complete the recommended treatment period before being considered. Aspirin can be continued through the perioperative period.
- **Peripheral arterial disease (PAD):** Pelvic CT scans can be leveraged to assess for arterial calcifications and ensure kidney transplantation remains technically feasible. For patients who have a history suggestive of underlying PAD, such as claudication or rest pain, noninvasive studies such as ankle-brachial index calculations and early referral to vascular surgery are recommended. If patients have a history of aorto-iliac occlusive disease that has been treated, they can still be transplanted

if vessels (pelvic or intraabdominal) on preoperative imaging remain suitable for implantation of the graft.

- **Malignancy and preoperative cancer screening:** As the age of the patients requiring kidney transplantation continues to increase, we are encountering more patients who have previously been treated for malignancies. Here, we will focus on the most common malignancies encountered during kidney transplantation evaluation.
    - **Breast cancer:** Low-risk breast cancer patients, such as those being treated for ductal carcinoma in situ (DCIS) or stage I breast cancer, can be transplanted after completion of their recommended treatment without any waiting period. Length of endocrine therapy should not influence the decision to transplant. For high-risk breast cancer patients (stage III and above), a waiting period of 3 to 5 years after completion of standard therapy is recommended. Patients with inflammatory and metastatic breast cancer should not be transplanted.[7] Females who are 50 years of age and older should have a screening mammogram every 2 years while waiting for transplant.
    - **Colorectal cancer:** Patients with low-risk colorectal cancer (stage I and II) can be considered for transplantation after completion of treatment and remaining disease-free for 2 years. Those with high-risk cancers (stage III or IV) should be considered after completing treatment and being cancer-free for 5 years.[7] High-risk features include lymphovascular invasion, perineural invasion, signet net histology, poor differentiation, tumor perforation, inadequate lymph node assessment, and node-positive disease, all of which increase the risk of cancer recurrence even in nonmetastatic disease.[8] Screening colonoscopy is required for all standard-risk patients aged 45 years and older.
    - **Renal cell carcinoma (RCC):** ESKD patients are at increased risk of RCC. Most renal masses are incidentally discovered and are less than 4 cm in size. Those that are less than 4 cm can be safely monitored, but current standard practice is treatment of all masses suspicious for RCC, either through ablation or nephrectomy. If the rate of growth is more than 0.5 cm/year, or when the mass becomes 4 cm or greater, definitive treatment is indicated before proceeding with transplantation.[7,9] Incidentally discovered renal tumors less than 1 cm in size can be monitored.
    - **Prostate cancer:** Prostate cancer is the leading cause of cancer in males. All male patients 50 years and older are screened with a prostate-specific antigen (PSA) test. A repeat PSA screening every 1 to 2 years is recommended.[10]
    - **Gynecologic cancers:** Females 21 years and older are screened for cervical cancer with a Pap smear before being placed on a waiting list. Pap smears should be repeated every 3 years if normal. Low-risk gynecologic cancers that have risk of recurrence of less than 5% do not require any waiting period after completion of therapy. These include early stage (stage I, grade 1–2) endometrial; stage IA/B/C, grade 1 to 2, epithelial ovarian; and stage IA squamous/adenocarcinoma of cervix. With intermediate-risk cancers that have a 5% to 15% risk of recurrence, a 3-year wait time after completion of primary therapy is usually recommended. These include stage I and II endometrial cancers with high-risk features and stage IB cervical cancers. With high-risk disease with a recurrence chance of greater than 30%, a wait time of 5 years is recommended. These include high-stage endometrial, ovarian, and cervical cancers, except stage IV disease, in which case patients are not considered candidates for transplant.
- **Infectious workup:** Patients undergoing transplantation will be initiated on immunosuppression; hence, part of the evaluation process involves comprehensive assessment for any underlying infectious disease process. Generally, any active viral, bacterial, or fungal infections will need to be adequately treated before transplantation. Active tuberculosis needs to be treated, and screening should be done on all potential recipients with chest x-ray and either purified protein derivative (PPD) skin test or interferon-gamma release assay. Urinary tract infections will be frequently encountered and should be treated before transplant. Patients with a history of renal cyst infections (e.g., polycystic kidney disease patients) should be managed on a case-by-case basis. Although the Kidney Disease Improving Global Outcomes (KDIGO) guidelines do not recommend routine preoperative prophylactic nephrectomy in these patients, a case may be made for those patients with other symptoms in conjunction with recurrent infections, such as considerable pain, recurrent cyst infections, or history of sepsis from cyst infections.[5] Human immunodeficiency virus (HIV) infection, if adequately treated and controlled, is not a contraindication to transplantation. HIV-positive recipients should be selected based on institutional criteria, just as with other standard recipients. HIV-positive recipients can receive kidneys from HIV-positive donors, which has decreased wait times for these patients in some parts of the United States from 8 years to less than 1 year.[11] HIV nephropathy may recur, and therefore, these patients should be closely monitored. Hepatitis C (HCV)-positive recipients should be assessed for possible underlying cirrhosis and the presence of an active infection. If decompensated, they need to be referred for simultaneous liver-kidney transplant evaluation. If there is active infection, it should ideally be treated before transplant unless patient consents to an HCV-positive organ and there is probability of being transplanted soon after being listed. Patients with mild stages of fibrosis or early cirrhosis can be transplanted in cases where they do not have portal hypertension. If there is evidence of invasive fungal infection, that needs to be appropriately treated before transplant, whereas mere colonization by fungi is not a contraindication for transplantation. Screening for *Coccidioides* species in endemic areas is important because a history of pretransplant active disease or seropositivity might require azole prophylaxis for life. With regard to parasitic infection, *Toxoplasma* screening should be done in all patients undergoing organ transplantation. *Strongyloides* and *Trypanosoma cruzi* screening should be done in highly endemic areas (Table 52.1).[12]

KIDNEY ALLOCATION SYSTEM

Presently, the US transplant system faces multiple challenges in kidney allocation, particularly with regard to equity. As a result of the increasing ability of centers to list more complicated patients as well as an ever-growing CKD/ESKD population, the wait list has progressively increased. The supply of organs has remained relatively constant, and as such, waiting times for a deceased donor kidney in some areas of the United States approach 10 years. Given the large gap between supply and demand, allocation rules exist and are founded on the basic premise of allocating organs to

TABLE 52.1 **Recommendations for Initial and Follow-up Screening of Viral and Nonviral Pathogens in Kidney Transplant Candidates**

PATHOGEN	TEST	REPEAT TESTING
Viral Infections		
HIV	IgG	If negative, repeat annually and at time of transplant
HCV	IgG	If negative, repeat annually and at time of transplant
HBV	Anti-HBs, anti-HBc, HBsAg	If negative, repeat annually and at time of transplant
CMV	IgG	If negative, repeat at time of transplant
EBV	VGA IgG or EBNA IgG	If negative, repeat at time of transplant
HSV	IgG	If negative, repeat at time of transplant
VZV	IgG	If negative, repeat at time of transplant and 4 weeks after vaccination
Measles, mumps, rubella	IgG	If negative, repeat at time of transplant and 4 weeks after vaccination
HTLV	IgG	None unless ongoing risk of exposure
Nonviral Infections		
Syphilis	IgG with confirmatory testing if IgG positive	None
Strongyloides	IgG	None
Chagas disease	IgG	None
Tuberculosis (in low prevalence areas)	Tuberculin skin test or Interferon-gamma release assay (IGRA)	Annually if ongoing risk of exposure
Malaria	Blood smear if clinically indicated	None

CMV, Cytomegalovirus; *EBNA,* Epstein-Barr virus nuclear antigen; *EBV,* Epstein-Barr virus; *HBc,* hepatitis B core antibody; *HBs,* hepatitis B surface antibody; *HBsAg,* hepatitis B surface antigen; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HSV,* herpes simplex virus; *HTLV,* human T-lymphotropic virus 1; *VGA,* viral capsid antigen; *VZV,* varicella-zoster virus.

Adapted from Chadban SJ, Ahn C, Axelrod DA. KDIGO clinical practice guidelines on the evaluation and management and management of candidates for kidney transplantation. *Transplantation.* 2020 Apr;104(4S1 suppl 1):S11-S103.

the sickest first and doing so without introducing or exacerbating disparities based on race/ethnicity, sex, or geography. Allocation processes aim to match higher-quality kidneys with those individuals with highest expected posttransplant survival within a certain geographic parameter around the donor hospital. Pediatric patients therefore take priority for objectively better organs, with kidneys with a kidney donor profile index (KDPI) <35% matched to them first. There are also efforts to prioritize disadvantaged population subgroups, such as individuals with a high panel reactive antibody (PRA; e.g., difficult to find a compatible match) or previous living kidney donors. It is a constantly evolving process, and at the time of writing this chapter, allocation policies remain in flux as the transplant community moves toward continuous distribution policies. Intricate details regarding existing and proposed allocation policies are beyond the scope of this chapter.

DECEASED DONOR KIDNEY EVALUATION

Selecting an appropriate kidney for a recipient is a complex decision-making process that takes into consideration multiple variables. Donor history, serum creatinine trend, urine output, kidney biopsy results, kidney anatomy, and KDPI are just some of the factors initially assessed. KDPI aims to score donor kidneys (scale: 0%–100%), with kidneys with the highest KDPIs projected to have the worst graft survival. KDPI uses several variables, including donor age, height, weight, ethnicity, history of hypertension, history of diabetes, cause of death, serum creatinine, HCV status, and whether the donation occurred after brain death or circulatory death. However, KDPI alone may not always be helpful in discerning appropriate kidneys from marginal ones. For example, KDPI can be falsely elevated in the setting of acute kidney injury, which may improve over time. Comorbid conditions such as diabetes and hypertension may not always be known from history. Hemoglobin A1c (HbA1c) can give an indication about the level of diabetic control in a donor or raise suspicion of undiagnosed diabetes. Long-standing uncontrolled diabetes should be an indication for considering kidney biopsy even in the setting of normal serum creatinine or low KDPI. If hypertension is not diagnosed, one should be suspicious if the patient died of a hemorrhagic stroke, especially if a young donor.

Moreover, if the donor required renal replacement therapy during the organ-allocation process, it does not necessarily mean that the kidneys are not useable. Here, it becomes crucial to carefully assess kidneys once they have been procured to ensure they have not infarcted, and kidney biopsy is helpful in these scenarios to help rule out thrombotic microangiopathy, fibrin thrombi, or necrosis.

Generally, donor-recipient size mismatch has not been considered in adult kidney transplantation, but there is an increasing breadth of data suggesting that size difference does have an impact on the outcomes of the kidney transplant recipient. It is still unclear which anthropometric measurement is most dependable when matching donor-recipient size. Height differences between donor and recipient have been shown to have a correlation with outcome; for example, the use of kidneys from shorter donors in tall recipients leads to worse transplant outcomes.[13] On the other side of the spectrum, using larger kidneys in smaller recipients should also be carefully considered. Although unusual, having a large kidney implanted in a smaller recipient may lead to an inability to close fascia primarily or lead to vessel compression.

Frozen-section biopsy of kidneys has always been a contentious topic. Numerous studies now suggest minimizing use of kidney biopsy when choosing deceased donor kidneys. One of the commonly listed reasons for organ decline is kidney biopsy results. Most recently, published Organ Procurement and

Transplantation Network (OPTN) data demonstrated that nationally, the kidney discard rate has reached 25%. Performance of a kidney biopsy increases the odds of discard by three times, even when adjusted for donor characteristics. This association is strongest for low-risk (KDPI <20) kidneys.[14] There is a marked difference in histologic findings in sequential biopsies of the same kidney, with first biopsy findings having no association with posttransplant outcomes.[15] Therefore, across the United States, there is a movement to limit kidney biopsy on standard-criterion donors. OPTN has attempted to standardize the reporting of kidney biopsy results. In general, kidney biopsy reporting includes percentage of globally sclerotic glomeruli, presence or absence of nodular mesangial glomerulosclerosis, percentage of interstitial fibrosis and tubular atrophy, percentage of vascular disease/arteriosclerosis, and presence or absence of cortical necrosis and fibrin thrombi. Most centers across the United States use a threshold of 10% to 20% of glomerulosclerosis as a threshold for acceptance[16] because glomerulosclerosis >20% has been shown to positively predict graft loss.[17] However, in otherwise healthy patients who are 50 years of age and older, about 20% glomerulosclerosis may be observed; hence, certain kidneys with high glomerulosclerosis (up to 20%) may be considered after weighing donor history and recipient characteristics. Kidneys with a higher percentage of glomerulosclerosis may be appropriate in recipients with lower body mass index (BMI). Another option when considering kidneys with high glomerulosclerosis is to use both kidneys in the same recipient.

Historically, most centers decline kidney allografts that have fibrin thrombi on biopsies. Studies have shown that kidneys with fibrin thrombi can be safely used, with good outcomes, after ruling out any significant cortical necrosis. Diffuse glomerular fibrin thrombi are often observed in the setting of a donor cause of death from severe head trauma. Kidneys with diffuse glomerular fibrin thrombi seen on biopsy have a higher incidence of DGF, but overall, >90% are associated with good clinical outcomes.[20]

Donor cross-sectional imaging can be very useful in assessing blood vessels and give an indication of the degree of atherosclerosis. At the time of procurement when assessing kidney anatomy, the surgeon comments on their subjective assessment of the degree of atherosclerosis of the aortic patch and renal artery orifice. Hypothetically, having significant atherosclerosis of the renal artery should correlate with microscopic arteriosclerosis of smaller renal vessels, and this rationale has been used by centers to decline those kidneys with marked gross atherosclerosis. However, it has been shown that there is no correlation between the two.[18] The most obvious reason for this is the subjective differences in evaluation of gross macroscopic disease by different surgeons. Main renal artery arteriosclerosis is not associated with delayed graft function (DGF), eGFR at 1 year, or long-term graft survival.[18] Microscopic arteriosclerosis, on the other hand, is associated with posttransplant allograft outcomes. Allografts with arteriosclerosis have a higher incidence of calcineurin inhibitor nephrotoxicity and posttransplant anemia, as well as poorer long-term function.[19] Kidneys with mild to moderate arteriosclerosis can still be used in select recipients. When using such kidneys, one needs to be aware of their physiologic demand for higher blood pressure to maintain perfusion, especially in the initial postoperative period. Because of the high degree of discordance observed when reporting arteriosclerosis on frozen section versus permanent, it is prudent to rely more on other parameters when considering kidneys with high percentage of arteriosclerosis. Donor history and hypothermic perfusion pump numbers offer additional data points to correlate with the degree of arteriosclerosis observed on frozen section. Allografts with abnormally reported histology are expected to have higher resistance and lower flow rates.

Recent severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2, COVID-19) pandemic affected the field of transplantation as centers became rightfully wary of use of any donors that were COVID-19 positive. This was to protect not just the transplant recipients but also the healthcare teams involved in the process. At the outset of the COVID-19 pandemic, when there were limited therapies for treatment, no available vaccination, and a lack of understanding of modes of transmission, kidneys from donors infected with COVID-19 were universally declined because angiotensin receptors, which are expressed in kidneys, were identified as potential receptors for COVID-19 and could promote transmission.[21] With changing strains of the virus potentially leading to less severe disease, transplant center practices have evolved, and kidneys from low-risk COVID-positive donors are being accepted and transplanted. Low-risk features include a longer time since initial positive test, mild disease severity or no systemic signs, cycle threshold >35, no acute respiratory distress syndrome (ARDS), and no thrombosis. Kidney transplantation from carefully selected COVID-positive donors does not negatively affect early patient and graft survival.[22] There is a paucity of data on long-term outcomes.

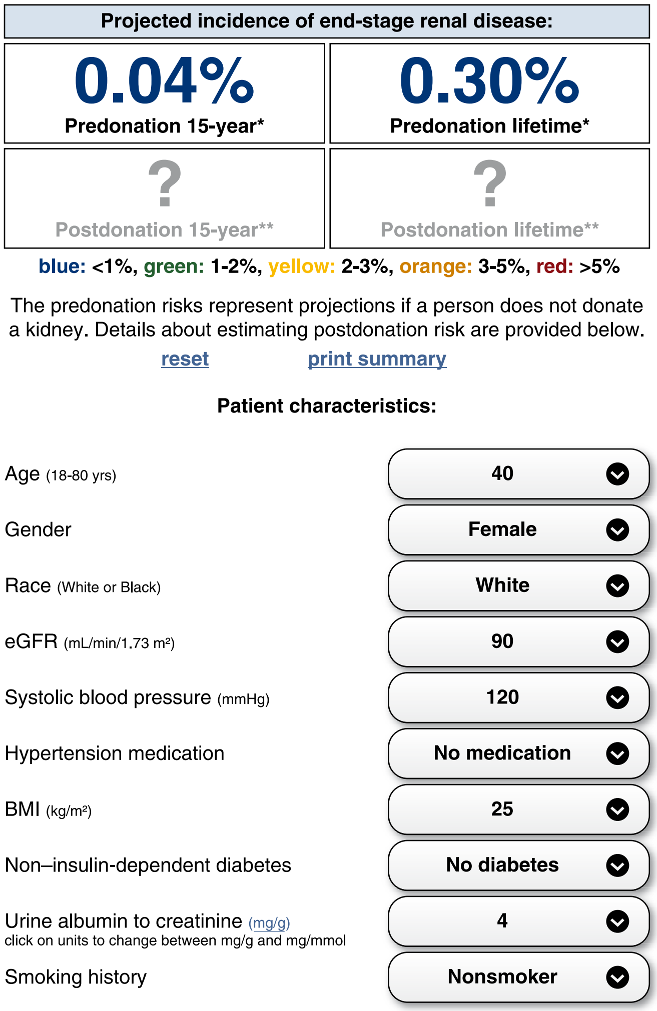
LIVING KIDNEY DONOR SELECTION

Living kidney donors are crucial to close the organ-shortage gap. In the United States, living donor kidney transplants represent 30% of all kidney transplants performed annually. Every center in the United States has an established workflow around the evaluation of potential living kidney donors. The United Network for Organ Sharing (UNOS) and KDIGO are the two organizations that provide guidelines around the testing and workup of potential living kidney donors. An essential part of the approval process is to ensure that there is minimal risk to the donor in immediate term and minimal risk of developing ESKD in the long term after donation. These individuals are otherwise healthy people who are undergoing an operation they individually do not need. Therefore, any morbidity and mortality associated with the process of kidney donation is taken very seriously.

Historically, it was assumed that donating a kidney was not associated with increased risk for future development of ESKD, but more recent studies have demonstrated increased risk compared with healthy nondonor controls.[23] Particularly among vulnerable subpopulations, such as African American persons and obese persons.[24-26] Moreover, metabolic changes associated with kidney donation may, over time, increase risk of CVD. Recent reviews have shown that if the follow-up is extended beyond 15 years, there is an association of kidney donation with increased cardiovascular and all-cause mortality.[27] Kasiske et al. followed living donors for 9 years after donation and demonstrated that the donors had higher parathyroid hormone, homocysteine, and uric acid levels, and their mean small artery elasticity was significantly lower. However, at 9 years, donor and control urine protein, urine albumin, glucose, HbA1c, lipoprotein levels, and blood pressure were not much different.[27] Although it is important to note that most risks are reported as relative and the absolute postdonation risks remain very low, it is critical that all potential risks, no matter how small the magnitude, be communicated to persons considering living kidney donation, particularly for vulnerable subpopulations, to ensure the fidelity of the informed consent process:

- **Females:** Davis et al. reported that females who get pregnant after kidney donation do not have a statistically significant increased risk of preeclampsia/eclampsia, but there was a trend toward preeclampsia in the kidney donor group compared with controls.[28] Although there is a dearth of comprehensive data to suggest a proven increased risk of hypertension-related complications during pregnancy, females should be counseled adequately about these potential concerns.
- **Obese persons:** Increasing numbers of obese individuals are being evaluated as potential donors because the prevalence of obesity in the United States is on the rise. Various studies over the years have tried to establish a BMI cutoff, above which the risks of harm to the donor postdonation are substantial enough to warrant an absolute contraindication to living donation. Even donors who are overweight (BMI >27 kg/m^2), however, have been shown to have an increased risk of developing ESKD, although the strongest association remains among donors with a BMI above 30 kg/m^2.[24,25] Obese donors have an almost twofold higher risk for ESKD in comparison to nonobese donors. Apart from increased risk of developing ESKD, obese donors are at an increased risk of all-cause mortality, which has been reported as 30% higher compared with nonobese donors, regardless of development of ESKD.[24,25] With increasing average BMI of potential living donors, centers need to ensure it is communicated to the donors that with a BMI beyond 27 kg/m^2, there is an increased risk of end-stage renal disease (ESRD). Ideally, donors who are otherwise approved for donation but have a BMI above 30 should be counseled about weight loss before proceeding with kidney donation.
- **African American persons:** African American persons have a higher incidence of hypertension and ESKD compared with other ethnicities, and they have a statistically significant risk of developing hypertension and ESKD after kidney donation.[27,29] Therefore, when counseling African American donors, they should be informed of their increased risk for developing hypertension and ESKD after kidney donation.

When evaluating the potential living donor, it is the responsibility of the transplant center to perform a detailed consultation in which all the risks are explained in detail. Risk assessment is individualized for each patient. Although there are calculators available that can estimate an individual's lifetime risk of acquiring ESKD before donation, there are multiple variables that are not included in these calculators. One of the tools that is available online (http://www.transplantmodels.com) attempts to give a quantitative value to the risk of developing ESKD before kidney donation.[30] This is one tool that can allow physicians to appropriately counsel donors based on their individual risk (Fig. 52.1).



Projected incidence of end-stage renal disease:

0.04%
Predonation 15-year*

0.30%
Predonation lifetime*

The predonation risks represent projections if a person does not donate a kidney. Details about estimating postdonation risk are provided below.

reset print summary

Patient characteristics:

Age (18-80 yrs): 40
Gender: Female
Race (White or Black): White
eGFR (mL/min/1.73 m^2): 90
Systolic blood pressure (mmHg): 120
Hypertension medication: No medication
BMI (kg/m^2): 25
Non–insulin-dependent diabetes: No diabetes
Urine albumin to creatinine (mg/g): 4
click on units to change between mg/g and mg/mmol
Smoking history: Nonsmoker

FIGURE 52.1 End-stage renal disease (ESRD) risk tool for kidney donor candidates. Example illustrates a hypothetical patient and their estimated lifetime risk of ESRD before donation. *BMI*, Body mass index; *eGFR*, estimated glomerular filtration rate. (From http://www.transplantmodels.com.)

The standard evaluation appointment for the donor involves obtaining detailed history of the patient, including medication history and family history. Psychosocial assessment should ideally be done by a provider not involved in the care of the potential recipient. Assessment should be done in the absence of other family members who may influence the decision of the donor. Coercion needs to be ruled out during the interview. Social history is very important because once someone is found to be suitable as a donor, it is necessary to ensure adequate social support is in place to assist with postdonation recovery. Things to consider in these situations include work-related needs (e.g., time off) and any childcare obligations that may need to be covered.

On physical exam, attention needs to be paid to blood pressure, any previous abdominal surgical scars, and any hernias. Two blood pressure readings should be taken in the office to assess for white-coat hypertension. Ambulatory blood pressure monitoring is not required but is a common practice among centers to assess multiple blood pressure readings over multiple days.[31] For donors with borderline blood pressure, a blood pressure log helps in having a better understanding of their mean blood pressure. Individuals with uncontrolled hypertension are not candidates for donation. Individuals with controlled hypertension on a maximum of two agents may be considered with caution.[32] They need to be counseled in depth about their increased risk of developing ESKD and worsening hypertension with one kidney.[30,33]

These are rare circumstances. Most centers turn down individuals who have hypertension as potential donors.

Evaluation workup is extensive. Blood group needs to be tested and confirmed with a second test. Subtyping of blood group A donors is needed if the intended recipient has anti-A antibodies. Human leukocyte antigen (HLA) typing for major histocompatibility complex (MHC) class I and class II antigens, which are known to be most immunogenic, needs to be performed. Subsequently, the recipients are tested for donor-specific antibodies against these antigens.

As highlighted earlier, the most important part of the evaluation is establishing baseline kidney health of the donor. Per the 2019 commentary on the KDIGO 2017 guidelines, predonation kidney function evaluation involves measuring glomerular filtration rate (GFR) and not relying on serum creatinine concentration. The donor GFR needs to be expressed in mL/min/1.73 m^2. The first GFR can be the eGFR, most commonly calculated from serum creatinine concentration. The eGFR needs to be confirmed using one or more of the following calculations:

1. Measured creatinine clearance using 24-hour urine collection[34]
2. Measured GFR using an exogenous filtration marker, preferable urinary or plasma clearance of inulin, urinary or plasma clearance of iothalamate, urinary or plasma clearance of 51Cr-EDTA, urinary or plasma clearance of iohexol, or urinary clearance of technetium-99m diethylenetriamine pentaacetate (^{99m}Tc-DTPA)
3. Estimated GFR from a combination of serum creatinine and cystatin C
4. Repeat eGFR from serum creatinine

GFR value of 90 mL/min/1.73 m^2 is considered acceptable for donation. Between the value of 60 and 90 mL/min/1.73 m^2, each candidate needs to be assessed individually to establish if risk is acceptable. Candidates with GFR below 60 mL/min/1.73 m^2 should not be considered for donation.

Urine is tested for proteinuria, and as part of the initial screening, the ratio of urine albumin to creatinine on a spot sample is assessed. Subsequently, to quantify albuminuria, a timed urine sample is collected. Candidates with an albumin excretion rate (AER) of less than 30 mg/d can donate safely; those above 100 mg/d should not donate. Urine is also assessed for hematuria. If hematuria is detected, it can be confirmed with another sample. Cause of hematuria may be simple, such as a bladder infection or kidney stones. Some cases may warrant a cystoscopy to rule out bladder cancer or other urothelial malignancies. Eventually, patients with unexplained hematuria with no other identified cause will need a kidney biopsy to rule out pathologies such as Alport syndrome, IgA nephropathy, and thin basement membrane nephropathy disease. If nephrolithiasis is discovered, previous stone history needs to be obtained and recurrence risk assessed. Biochemical analysis can be done, which provides details of stone composition and may highlight underlying metabolic issues as a cause of recurrent stones, in which case it becomes unsafe to proceed with donation. It is important to consider that donors with one kidney will have much less tolerance for maintaining adequate renal function if they develop large stones in the remaining kidney. If an isolated kidney stone is discovered on imaging and the rest of the workup is not suggestive of risk of recurrent stones, the kidney with the stone should be donated.

Kidney donors undergo computed tomography angiography (CTA) of abdomen, and it is recommended that 3D reconstruction is done on those images to carefully assess anatomy before proceeding to the operating room. Cross-sectional imaging can be used to estimate the kidney volume. If there is a significant size difference between the kidneys, radionuclide scans can be used to assess individual kidney GFR. Radionuclide studies should also be conducted in situations where vascular anomalies or pelvic collecting system anomalies are encountered incidentally on preoperative imaging.

Donors with a history of type 1 diabetes should not donate. Those with type 2 diabetes are usually discouraged from donating because they have risk of progressive end-organ damage over the years. HbA1c and fasting blood glucose levels are checked as part of routine workup. History of active smoking is not an absolute contraindication for donating, but potential donors should be counseled about increased risk of developing ESKD with continued smoking after donation. Smokers may have poor-quality vessels, which may pose technical challenges when those kidneys are transplanted. Cross-sectional imaging can alert to any significant calcifications in the main artery, in which case the potential donor should not be approved.

Infectious workup includes testing for human immunodeficiency virus (HIV), hepatitis B (HBV), hepatitis C (HCV), Epstein-Barr virus (EBV), cytomegalovirus (CMV), and *Treponema pallidum*. These labs should be drawn within 28 days of donation as per regulations—ideally, as close as possible to the donation date. Donors need to be up to date with their cancer screening per their age group and recommended health screening protocols.

LIVING DONOR NEPHRECTOMY

Donor nephrectomy should ideally be performed with a minimally invasive technique using laparoscopic or robotic assistance. In those donors who have extensive surgical history, open technique may be justified. There is an increasing prevalence of robotic utilization in donor nephrectomies, although this method is not officially endorsed by KDIGO.[32]

Debriefing with anesthesia before incision is a critical step. This ensures both teams have rapport and continue communication throughout the case. Donors will be under general anesthesia for about 2.5 to 3 hours. After induction, a nasal or oral gastric tube is placed to keep the stomach decompressed. Urine output needs to be strictly monitored. Preoperative antibiotic prophylaxis to lower the risk of surgical site infection is recommended. Commonly, mannitol and/or furosemide are administered before cross-clamping. IV heparin between 2500 and 5000 units may also be requested before cross-clamping of renal vessels. Heparization needs to be reversed with protamine after removal of the kidney.

The surgeon should be present at the time of patient positioning. Before the patient is positioned, it is important to carefully mark planned surgical incision sites. In the approach described here, we describe a total laparoscopic technique without a hand assistance port specific to a left-sided nephrectomy. A suprapubic transverse 6-cm mark is made in location of a typical cesarean delivery site. This location is used for extraction of the kidney. A 12-mm supraumbilical incision site is marked, a 12-mm left flank incision site is marked, and a 5-mm subxiphoid site is marked. After the incision sites have been marked, the patient is positioned in right modified lateral decubitus position, with the left arm out and secured on an armrest. The bed is flexed to allow more working space by increasing the distance between the inferior rib margin and the anterior superior iliac spine. All bony prominences and pressure points are carefully padded. Entry is made at the supraumbilical port, which can be done with either Hasson technique or with a Veress needle. After pneumoperitoneum is established, appropriately sized trocars are placed in previously marked surgical sites. An additional trocar is placed at the suprapubic incision site through the planned incision mark to aid in retraction.

The key steps of the operation include the following:

1. Begin with mobilization of the descending colon medially, along the white line of Toldt, ensuring mesentery stays intact.

Release splenic flexure if needed to expose superior pole of the kidney. Medial extent of the mobilization ends with exposure of the ureter.
2. Identify the left ureter as it crosses over the common iliac artery.
3. Identify the gonadal vein and dissect cranially until it drains into renal vein.
4. Dissect renal vein along its superior and inferior border; identify adrenal vein superiorly and draining lumbar branches inferior or posterior to the renal vein. Ligate lumbar branches with a sealing device or stapler.
5. Identify renal artery, commonly along the inferior-posterior border of the renal vein; dissect circumferentially at the takeoff from aorta.
6. Once superior edge of renal artery is identified, it is safe to encircle the left adrenal vein and ligate.
7. Dissect adrenal gland off the superior aspect of the kidney.
8. Dissect the kidney off retroperitoneal fat with a vessel-sealing device.
9. Transect the gonadal with a stapler, and transect the ureter after doubly clipping distal ureter.
10. Position an EndoCatch bag in the midline after inserting it through the suprapubic port site.
11. Ensure diuretic per institutional protocol has been administered, and use a stapler to transect renal artery at the takeoff from aorta, followed by renal vein in a similar manner; maneuver kidney into the EndoCatch bag.
12. Swiftly extend the Pfannenstiel incision and open fascia superiorly and inferiorly, remove kidney, and pass it to the back table for flushing.
13. Bring peritoneum and fascia of extraction site together with clamps and reestablish pneumoperitoneum.
14. Ensure hemostasis at the stump sites.
15. Ensure descending colon mesentery is intact and position colon in anatomic location.
16. Close fascia at 12-mm port sites; close fascia at extraction site.

POSTOPERATIVE COURSE AND COMPLICATIONS

Most living donors are discharged home within 24 to 48 hours after the operation. Urine output is closely monitored postoperatively; hence, a Foley catheter is left in until postoperative day 1. Postoperatively, a low urine output should raise suspicion of possible bleeding or urine leakage from the ureter stump. Both need to be addressed expeditiously, with return to the operating room if confirmed. On postoperative day 1, it is safe to remove Foley catheter. If patient is unable to void, its cause should be evaluated. In the case of a full bladder with inability to urinate, a Foley catheter may need to be replaced and another void trial attempted the day after. An empty bladder can be a result of numerous causes. If underresuscitation is suspected, a fluid bolus may be needed. It is important to decompress the bladder because there is a higher risk of failure of Weck clips on the ureter if bladder is under pressure from distal obstruction, which will lead to intraperitoneal urine leakage, necessitating an exploration.

The most common postdonation complaint living donors experience is that of pain at incision sites and in shoulders. Shoulder pain is a result of diaphragm irritation postinsufflation. A multimodal regimen that includes narcotics and muscle relaxants is initiated to control pain. Early mobilization is necessary to prevent respiratory complications and decrease risk of deep venous thrombosis (DVT). By postoperative day 2, after ensuring appropriate pain control and bladder emptying, patients can be discharged home.

Rates of postoperative complications are low. Most studies report an incidence between 7% and 9.9 %.[35] Obesity is associated with higher risk of perioperative complications, with donors with a BMI >30 kg/m^2 at a higher risk. Most common complication in the postoperative period is ileus.

No donor nephrectomy technique has been proven to be superior to the other. There are differences in warm ischemia time, risk of bleeding, and operative time in between techniques, but all techniques are equally safe, and optimal approach depends on surgeon preference and training. Laparoscopic donor nephrectomy and robotic-assisted donor nephrectomies are reported to have the highest warm ischemia time, but this is not significant enough to have an impact on graft survival. Retroperitoneoscopic donor nephrectomy has the highest amount of blood loss.[35] After fatal incidents, the US Food and Drug Administration (FDA) issued a black box warning for use of Hem-o-lok clips on renal artery at the time of nephrectomy; hence, nearly all centers now use staplers to transect renal artery.

DECEASED DONOR KIDNEY PROCUREMENT

As previously mentioned, deceased donors can either be donation after brain death (DBD) donors or donation after circulatory death (DCD) donors. It is primarily the responsibility of the organ procurement organization, not the transplant center, to ensure that all required brain death testing has been completed before allocation begins. Brain death testing protocols differ between states. As an organ procurement surgeon, it is crucial to confirm that the donor's chart has brain death testing and confirmatory notes completed and that brain death declaration has been done by a physician not involved in the organ transplant process.

For DBDs, the procurement operation has a few critical steps with regard to kidney procurement:

1. Begin xiphoid process–pubic symphysis incision in midline.
2. Carefully examine all intraperitoneal surfaces and organs to ensure no occult malignancy.
3. Release right colon by dissecting along white line of Toldt until duodenum is visualized, followed by Kocherization of duodenum.
4. Identify left renal vein crossing over the aorta to drain into inferior vena cava, which usually signifies extent of this dissection. Cephalad, the superior mesenteric artery is palpable in the small bowel mesentery.
5. Similarly, medialize the left colon by lifting the mesentery off the left kidney and releasing the colon by working along the white line of Toldt.
6. Identify ureters on both sides crossing over the common iliac arteries on either side; isolate location of transection as distally as possible.
7. Expose aorta before iliac bifurcation and place two umbilical tapes for control—this will be the site of cannulation.
8. Expose supraceliac aorta if chest is not open; otherwise, an aortic clamp can be placed on descending aorta in the chest at the time of cross-clamping.
9. Heparinize with 50 to 80 units/kg of body weight of donor; while waiting for heparin to circulate, ligate distal aorta with umbilical tape.
10. Transect aorta with digital control of proximal aorta, and cannulate with an appropriate cannula (usually between 18 and 20 Fr).

11. Use the junction of the atrium and inferior vena cava (IVC) as the site of outflow and transect while at the same time clamping descending aorta to ensure all flush flows into abdominal organs. Open preservation solution flush. Place ice on all organs.
12. While flush flows, use a bowel stapler to transect small bowel past the duodenum, and similarly staple across the small bowel and right colon mesentery to release bowel out of the abdomen for better exposure.
13. Once flush is completed, remove the cannula, dissect all lymphatic tissue anterior to the aorta until left renal vein is reached, and transect at the exact insertion into the IVC to allow adequate length on the left renal vein.
14. Transect the IVC above the insertion of right renal vein, which may be higher than expected (Fig. 52.2).
15. Staying anterior on the aorta, transect the anterior wall open until the takeoff of superior mesenteric artery; visualize the orifices of right and left renal artery; and completely transect aortic wall above these orifices, leaving an adequate patch with the orifices intact. Transect the aorta in the midline.
16. Transect ureter on the right and release it out of pelvis, leaving adequate tissue (mesoureter) around the ureter to preserve microvasculature for its blood supply.
17. Transect inferior vena cave above bifurcation, release the IVC along with aortic patch off the spine, and dissect the kidney from retroperitoneal fat to bring it out of the body.
18. Release left kidney in a similar manner.

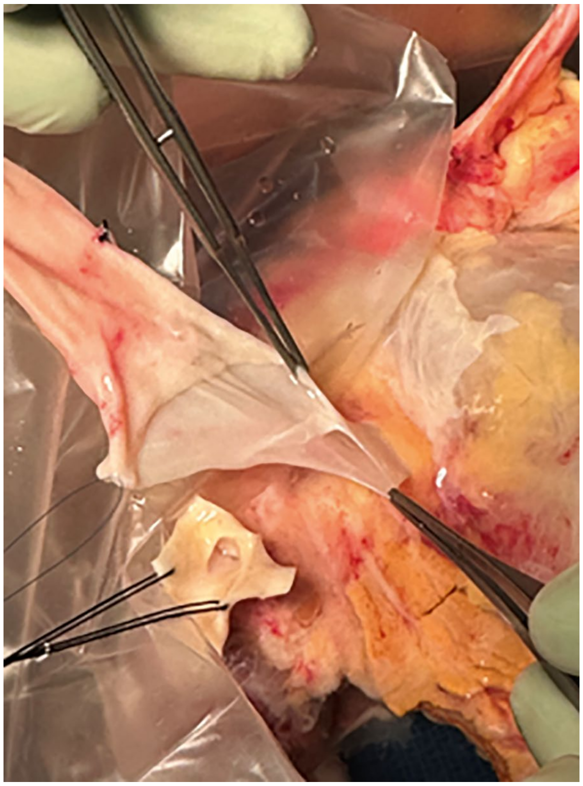

FIGURE 52.2 Procurement injury in a deceased donor in which the inferior vena cava (IVC) was transected below the right renal vein takeoff. This kidney was able to be used by reconstructing an extension graft. Donor IVC was completely transected and sewn end to end to the right renal vein.

For a DCD operation, the goal is to cannulate aorta as quickly as possible after donor has progressed. After getting into the abdomen from a midline incision, bowels are retracted superiorly, and blunt and sharp dissection is used to get down to aorta at the bifurcation. Once cannulated, a supra celiac aortic clamp is placed. This is followed by draining the venous system either in the abdomen at lower vena cava or in the chest. After flush is initiated, the remainder of the dissection occurs as described previously.

With recent advances in organ preservation techniques, it is becoming increasingly common that procured kidneys will be placed on a perfusion pump for storage. Hypothermic machine perfusion (HMP) continuously pumps cold preservation solution, in contrast to static cold storage, whereby after being flushed with preservation solution, the kidney is stored submerged in preservation solution with ice around it. There is a lower rate of DGF, along with improved long- and short-term graft survival in those kidneys that are placed on HMP pumps.[36] This is true for both DBD and DCD donors. It is therefore recommended to use HMP pumps where available. Parameters that can be assessed on HMP include renal resistance and flow rates. These parameters are only meant to assist in decision-making when using marginal kidneys and should not be the sole factor determining use versus discard of a kidney. Commonly agreed-on poor perfusion parameters include a renal resistance (RR) of >0.40 mm Hg/mL/min and flow rate less than 80 mL/min/100 g. However, these should only be used in conjunction with donor medical history and biopsy findings to assess concordance before considering discard.

BACK-TABLE PREPARATION OF KIDNEY GRAFT

Careful back-table preparation is crucial for a successful kidney transplant. There are no statistics or studies available at present to accurately predict how many kidney discards are a result of inadvertent procurement and/or back-table injuries.

The goal of the back table of a kidney graft is to have adequately exposed artery and vein with hemostatic control of all side branches. Removal of all extra adipose tissue around the kidney is recommended. Preparation of the ureter should focus on preserving the mesentery of the ureter. Closing of biopsy site if present and assessing for leaks at the completion of back table is strongly encouraged.

The kidney graft should be examined for any gross abnormalities or injuries that might make it not transplantable; for example, assess for any capsular tears, check that main artery is intact and orifice is patent, and similarly check that the vein is intact. Ureter entering the pelvic collecting system should be traced. At this point, it is usually acceptable to allow the recipient to be brought back to the room for induction and line placement while back-table preparation of the kidney is completed.

Kidney should be positioned in its anatomic position in the basin. Gentle traction on artery and vein can be accomplished through silk sutures at the corners of arterial patch and edge of vein. For left kidney, vein is prepared first. Dissection stops before the vein enters the renal hilum. This is followed by clearing the artery, ensuring no early branches to the kidney are inadvertently tied off. Vessel probes can be used to assess the trajectory of arterial branches. Methylene blue injection can be used to assess amount of parenchyma supplied by arterial branches. This can be useful when deciding to potentially ligate superior pole branches in situations where preservation of those branches will make the anastomosis challenging. Branches that supply less than 10% of the parenchyma can be safely ligated.[37] Some studies have assessed lower pole arterial branches to delineate ureteral blood supply. In our experience, lower pole branches need to always be preserved and separately prepared on back table if they are far apart on the aortic patch. It is crucial to visualize the whole artery because there may be areas close to hilum that have been injured during procurement (Figs. 52.3 and 52.4). Once vessels have been prepared, perinephric fat is cleared from the kidney. On the posterior aspect of the kidney, the surgeon should ensure that clearing of fat does not extend onto the pelvic collecting system, particularly when there is an extrarenal pelvis.

Biopsy site, if present, should be closed. It can be closed with a chromic suture in an interrupted U-stitch manner, or the site can be closed with running Prolene suture. One needs to ensure biopsy site is not too deep because that increases the risk of inadvertent injury to collecting system, which can lead to urine leak. Biopsy should not be done on inferior pole. If that is encountered, retrograde injection of diluted methylene blue can be used to assess if there is any brisk leakage. If that is encountered, reassessment can be done after repair to decide whether the kidney can be used. Preservation solution can then be injected into the artery and vein to assess for any major leaks.

Right kidney from a deceased donor comes with the IVC. Back-table preparation is similar except for preparation of this conduit. The vena cava is cleared off all tissues, and branches are ligated. Right renal vein is very thin, and generally, no sharp dissection is done to clear the tissue off the right renal vein. Small branches can be ligated carefully if they leak at the time conduit is tested. This vena cava conduit can be useful in scenarios where extra length is needed for a deep pelvis. This conduit can be prepared in different ways. For example, the superior caval orifice and orifice of takeoff of left renal vein can be joined and then closed with a running Prolene in two layers (Figs. 52.5 and 52.6).

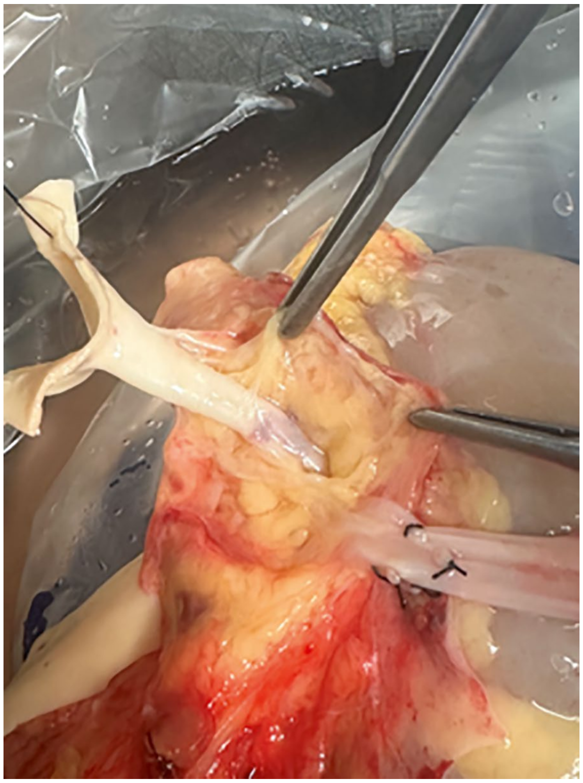

FIGURE 52.3 Renal artery dissection encountered at the hilum during back table preparation of kidney.

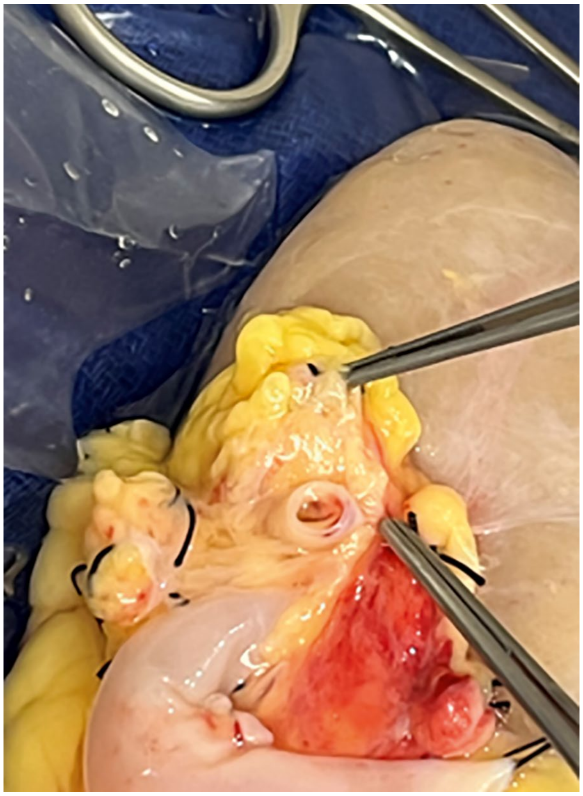

FIGURE 52.4 Artery was cut above the dissection to assess for possible reconstruction. Dissection extended past the first-order branches. This kidney was not used.

For right kidneys from living donors, venous conduit construction may be needed to have adequate vein length for anastomosis. Before a living right kidney donor is scheduled, it is important to ensure cadaveric vessels are available in case venous extension is required. If a venous extension is required, cadaveric iliac veins can be used. The cadaveric iliac vein, after being prepared, can then be anastomosed to right renal vein in an end-to-end manner. It is important to keep in mind that iliac vein may have valves; hence, with regard to orientation of conduit, anatomic caudal end of the iliac vein should be the end anastomosed to the renal vein.

KIDNEY TRANSPLANT OPERATION

A standard kidney transplant operation involves retroperitoneal placement of the kidney in right or left iliac fossa. During preoperative planning for kidney transplant, cross-sectional imaging is assessed to look for suitability of vessels for implantation. Because patients with long-standing ESKD will have calcifications of intimal and medial layers of the vessel wall, CT scans of the pelvis can guide placement of vascular clamps for arterial occlusion, avoiding calcified plaque areas. Similarly, it can help pick up the area most suitable for arterial anastomosis.

The preferred site of arterial anastomosis is the external iliac artery. If both external iliac arteries are severely calcified, the common iliac can be used for anastomosis. Previous surgical history of inguinal hernia repair will make retroperitoneal exposure challenging; hence, the opposite side to hernia repair

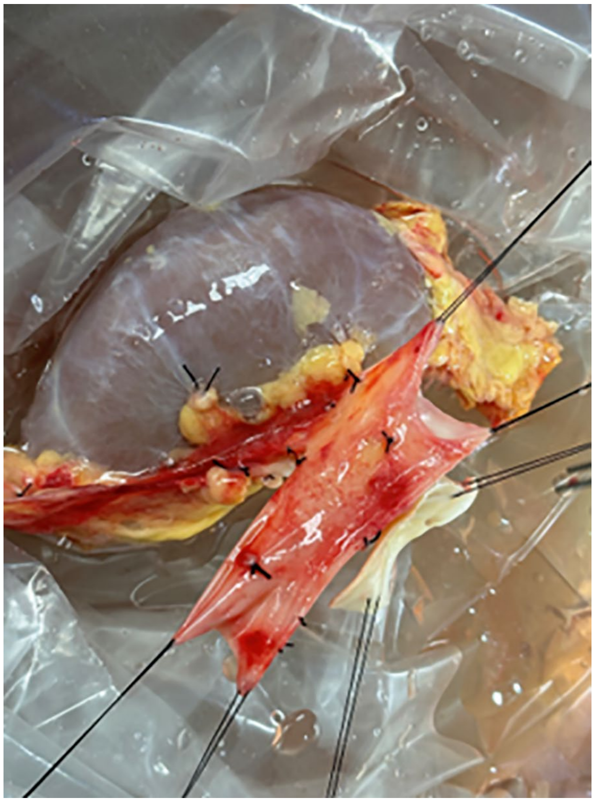

FIGURE 52.5 Right kidney on the back table with a cuff of inferior vena cava above the right renal vein.

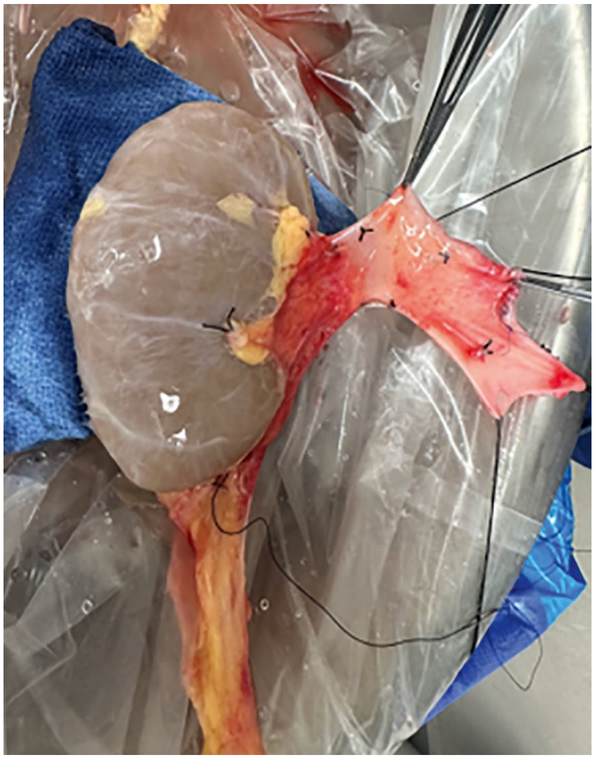

FIGURE 52.6 Reconstructed conduit for right renal vein with running Prolene across the top of vena cava extending onto left renal vein takeoff orifice.

may be better suited for implantation. With most inguinal hernia repairs now being done with laparoscopic techniques, patients may not remember the correct side during their history taking. CT scan will show signs of previous hernia repair, such as poor demarcation of planes on the side of hernia repair, and mesh can sometimes be visible as well on cross-sectional imaging. If there is hernia repair on the side with better blood vessels, it is generally recommended to still implant on that side even though vascular exposure on that side may be more challenging. Mesh can be traversed with heat cautery if encountered during dissection.

Anatomic landmarks that are helpful if marked on the abdominal wall include anterior superior iliac spine and pubic symphysis. A hockey-stick incision is made on the side where the kidney is going to be implanted. Incision should be roughly 2 to 4 cm medial to the anterior superior iliac spine (ASIS). The goal is to have minimal transection of musculature of lateral abdominal wall. Retroperitoneal space can be entered by transecting the linea semilunaris and gently moving the peritoneum medially. As the incision is extended cephalad, it may have to come through muscle layers of lateral abdominal wall as incision is extended laterally to have better exposure of right retroperitoneum. Caudally, incision is ideally extended to the pubic symphysis because this allows easier exposure of the bladder, especially in ESKD patients who have been anuric for multiple years and have atrophied and contracted muscular layers of the bladder.

When dissecting in the retroperitoneum, the round ligament in females can be ligated. In males, the spermatic cord is looped with a Penrose drain and retracted medially. Inferior epigastric vessels may be encountered in caudal aspect of the incision as they cross through the created space toward their course underneath the rectus abdominus muscle. These can be ligated if retraction is being limited as a result or if retractors may lead to them sheering. If ligated, leaving a longer stump at the proximal end allows for inflow options in situations of a known inferior pole artery or a missed artery, which may become evident after reperfusion of the kidney. After placement of retractors, external iliac artery and external iliac vein are exposed. All lymphatic channels anterior to the artery should be carefully ligated or coagulated. At the inferior aspect of the external iliac artery, one needs to be wary of a large crossing venous branch as it drains into the external iliac vein. Goal of exposure is to have an appropriate length of artery and vein for easy clamping and space for anastomosis. In atherosclerotic arteries, one needs to limit posterior mobilization of the artery because a circumferentially free artery can dissect and crack at sites of calcified plaque.

Minimize the amount of time needed for the kidney to be out of ice. Position the kidney in iliac fossa, and pull vessels to proposed site of anastomosis. In deceased donor kidney arteries, aortic patch can be used, and the vein should be cut to an appropriate length based on arterial length. Leaving an ice pack behind the kidney may allow the kidney to stay cold longer. Heparinization before clamping of vessels is a debated topic. There is no increased risk of postoperative hemorrhage if systemic heparin is administered; hence, it can be done in selected patients who may be at a high risk of vascular thrombosis. But overall, there is no difference in rates of thrombosis between patients who are administered systemic heparin before anastomosis versus those who are not.[38] Data are lacking to determine if systemic heparinization prevents venous thrombus formation of distal branches of clamped vein.

Venous anastomosis of the renal vein to the external iliac vein is performed first in an end-to-side manner with running 5-0 Prolene suture. This is followed by arterial anastomosis in an end-to-side manner between renal artery and external iliac artery with running 6-0 Prolene suture. For reperfusion, vein clamp is taken off first, followed by arterial clamp. The kidney is then warmed with irrigation. Hemostasis is secured.

Ureter is prepared by intentionally keeping it as short as possible for a tension-free anastomosis. Ureter is trimmed back to appropriate length, and if there is bleeding from the edges, this is a reassuring sign. Vascular bundles are ligated at the edge of the spatulated ureter. For ureteroneocystostomy, the bladder is backfilled with methylene blue–stained irrigation. Peritoneal reflection on superior and medial aspect of bladder is identified and swiped upward. Dissection on bladder wall is carried down through detrusor muscle to the mucosa. Mucosal entry should be made sharply, with anastomosis completed in two layers over a double-J stent. There is evidence that routine stenting of ureteroneocystostomy prevents major complications such as ureteral strictures and urine leakage.[39,40] The ureter is anastomosed to bladder mucosa with running polydioxanone (PDS) suture. Minimal handling of ureteral edges is recommended to prevent iatrogenic injury because ureteral wall is very fragile and can easily get crushed between tips of forceps. Second layer is of detrusor muscle on top of the ureter with a PDS suture. Once anastomosis is completed, Foley catheter can be unclamped to allow urine to start draining.

The length of time it takes to sew the kidney affects outcomes. The goal is to be swift but precise. Once out of ice, kidney should be reperfused, ideally in less than 45 minutes. An implantation time of more than 45 minutes increases risk of poor early graft function.[41] It is unclear if there is a difference in long-term outcomes. Some of the predictors of prolonged sew time include obese patients and use of right kidneys (because they are more likely to have multiple and longer arteries and more complex venous anastomosis).

SURGICAL COMPLICATIONS AND THEIR MANAGEMENT

1. **Transplant renal artery stenosis (RAS):** RAS is one the most common complications after renal transplant. Reported incidence is wide, ranging from 1% to 12%.[42] Early diagnosis is crucial for adequate treatment to prevent cortical necrosis and graft loss. Patients may present with worsening allograft function not explained by any other cause; refractory hypertension; and other signs of graft failure, such as fluid retention leading to volume overload. Patients with concern of RAS, based on ultrasound, should have confirmatory testing with a different modality, such as a magnetic resonance angiography (MRA). This limits administration of potentially nephrotoxic contrast to only at the time of therapeutic intervention such as angiogram and angioplasty. Ultrasound findings that suggest RAS include (1) an absolute peak systolic velocity (PSV) of 340 to 400 cm/sec at the anastomosis with normal waveforms, (2) a tardus parvus waveform, and (3) relatively reduced resistive indexes (Ris) from prior or RIs less than 0.5.[43] On an angiogram, a luminal narrowing of more than 50% with other concordant clinical findings suggestive of RAS should be treated. Most cases are resolved by percutaneous transluminal angioplasty with stent placement (Figs. 52.7 and 52.8). Not all renal artery stenoses will require intervention because routine postoperative surveillance imaging, such as Doppler ultrasound, can have findings that are consistent with RAS per radiologic criterion but have no clinical effect on the kidney.
2. **Renal artery thrombosis:** This is usually encountered in immediate postoperative settings, mostly within the first month after transplant. It is a surgical emergency and needs to be addressed promptly for any chances of graft salvage. Incidence is low at about less than 1%. Most of the cases are a result of technical issues. Intimal flap in the artery, external compression from a hematoma, dissection of the external iliac artery from clamp placement, and kinking of the artery at the time of fascial closure can all lead to renal artery thrombosis. Hyperacute rejection can also lead to renal artery thrombosis, but this is extremely rare, given advancements in immunologic matching between donors and recipients. Ultrasound will show an absence of arterial flow to renal parenchyma, and it can be confirmed by contrast-enhanced ultrasound. If patient was previously making urine, there may be an abrupt cessation of urine production, and there may be pain as a result of peritoneal irritation from an infarcting kidney. When encountered in the immediate postoperative setting, patient needs to be emergently taken back for exploration. The operating room team should be aware of the possibility of graft explant and reimplantation. If absence of flow is confirmed upon entry with visual inspection, inspection of vasculature, and Doppler examination, graft should be explanted by reclamping the vessels. Graft needs to be assessed on the back table and flushed with cold preservation solution. Artery needs to be assessed. If a dissection is present, it may not be salvageable if it extends into hilar branches; otherwise, an attempt should be made to cut back to healthy artery wall. If parenchyma flushes out well, this kidney may be able to be retransplanted. If there is a concern about timeline between renal artery thrombosis and reexploration, a kidney biopsy should be sent for frozen section. A finding of significant cortical necrosis will render the kidney not transplantable.
3. **Renal vein thrombosis:** This is a rare complication; the reported incidence in the literature ranges from 0.3% to 4.2%.[43] If it occurs in the immediate postoperative period, patients will have an abrupt drop in urine output, urine will appear sanguineous, and there may be pain from graft swelling. This can be life threatening because graft rupture can occur as a result

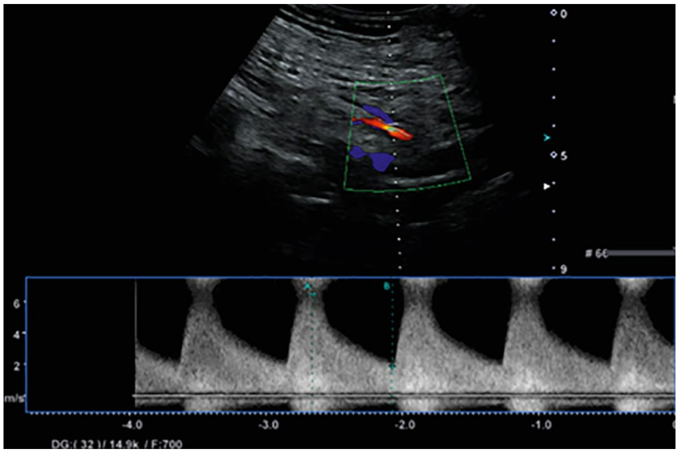

FIGURE 52.7 Ultrasound Doppler at 3 months after deceased donor renal transplantation of a 64-year-old male with increasing serum creatinine. Peak systolic velocity at the anastomosis is >600 cm/s.

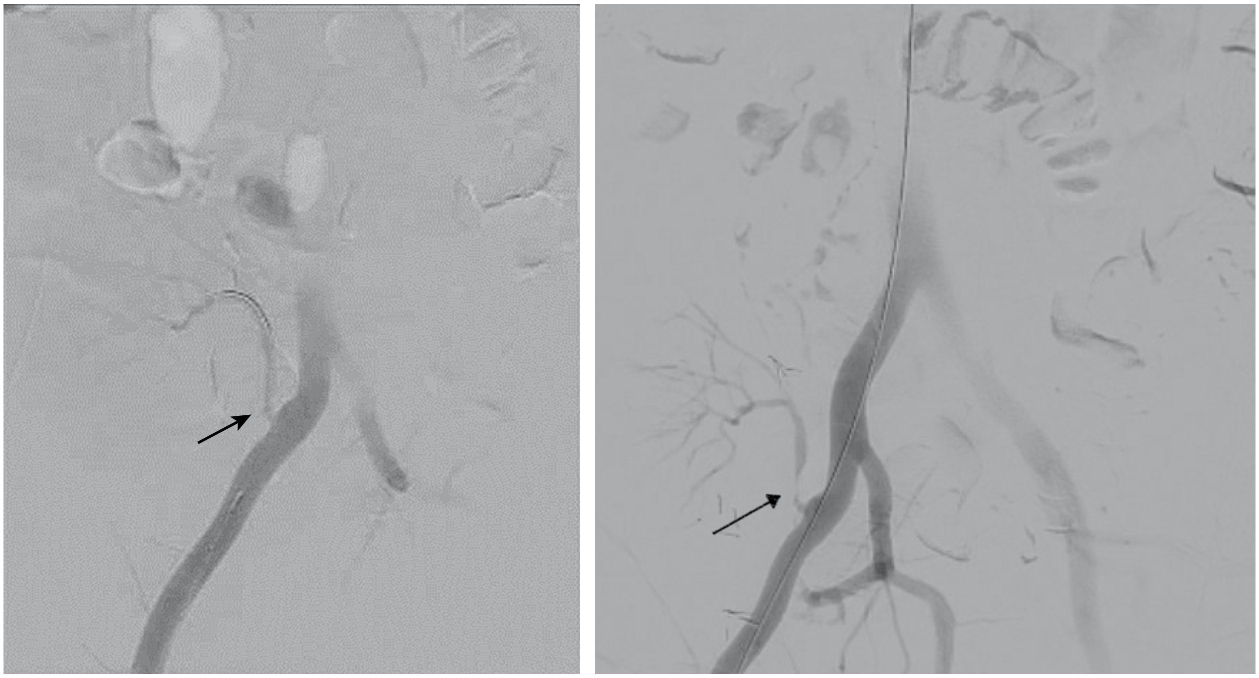

FIGURE 52.8 Angiogram of the same 64-year-old male before and after deployment of balloon expandable stent across the stenotic segment.

of patent inflow and occluded outflow. Ultrasound is the modality of choice and will show either a hypoechoic or anechoic clot; another characteristic finding is reversal of diastolic flow in renal artery on Doppler assessment. At the time of reexploration, direct thrombectomy can be attempted, and if unable to retrieve clot from renal vein, the team may need to explant the graft. Upon explant, graft needs to be flushed with cold preservation solution and assessed for viability before reimplantation.

4. **Peritransplant collections:** Depending on the time posttransplant, the differential for the etiology of fluid collection varies. Hematomas usually present within the first few days posttransplant. Patients may complain of pain in flank region because a hematoma can dissect into retroperitoneal fat on that side of the transplant. A drop in hemoglobin, along with an ultrasound showing peritransplant collection, will usually be sufficient to confirm the diagnosis. A noncontrast CT scan can better evaluate the extent of the hematoma as well. Reexploration and washout are recommended. The source of bleeding may not be found in most cases, but hematoma evacuation is necessary because it can compress vasculature and become infected, leading to future abscess formation. Small incidental hematomas that are found on surveillance ultrasound can be left alone. Peritransplant abscesses need to be dealt with aggressively and can often be managed percutaneously, but operative debridement should be strongly considered. Lymphoceles are another common collection that will be encountered in postoperative period. They are usually encountered between 2 weeks to 6 months after transplantation, with a peak incidence at 6 weeks.[44] There is a wide range of incidence reported from 1% to 50%.[45] Patients may present with symptoms of pain and pressure at site of transplant. On examination, surgical site swelling may be noticeable as well; there may be associated lower extremity swelling on the same side as a result of compression of iliac vein. Labs can demonstrate worsening renal function. Surgical technique matters when clearing iliac artery because multiple lymphatic channels cross anterior to the vessel. The large ones should be ligated, and smaller ones should be coagulated. Lymphatic channels from the transplanted kidney hilum can leak as well; hence, careful ligation of excess tissue is important. Management involves percutaneous drainage, which has a high failure rate. After simple drainage fails, it can be followed by povidone-iodine sclerotherapy, which is a safe modality for management of primary symptomatic lymphoceles.[46] Surgical management involves creating a peritoneal window, which can be done both laparoscopically and open. When making this peritoneal window, careful attention needs to be paid to preoperative imaging to stay clear of ureter and hilar vascular structures. Once this fluid is drained, it should be sent off for Gram stain and culture. Fluid creatinine should also be assessed to rule out a urine leak.
5. **Urologic complications:** Most ureteral complications stem from a failure to preserve its blood supply during either procurement or back-table preparation. Transplanted kidney ureter is dependent on blood supply through the mesoureter. Any tissue on the inferior pole of the kidney surrounding the ureter needs to be preserved. Preservation of the inferior pole artery, if present, is critical because in those kidneys, the ureter will be dependent on it for the blood supply. Ureteral stenosis presents a few weeks to months after transplant; it is reported in the literature to have an incidence of 2.6% to 15%.[47] Patients will present with worsening renal function with hydronephrosis on ultrasound. Acute hydronephrosis can be managed by placement of a nephrostomy tube. A retrograde placement of a double-J stent can also be attempted, but in some cases, severity of stenosis may prevent a wire from passing. An antegrade nephrostogram can help assess the length of the

stenosis. Minimally invasive techniques that can be attempted before open surgery, such as balloon stenting and self-expanding metal stent placement, have been described in the literature. Open surgical technique depends on size and location of the stricture. If it is a short-segment stenosis at the anastomosis, it can be fixed by reimplantation of the healthy ureteral edge into the bladder. If stenosis is a long segment or too proximal, a ureteropyelostomy is needed, using the native ureter. In delayed presentations of ureteral stricture, it is important to rule out BK viremia. Urine leak in immediate postoperative period is either a result of surgical error or distal ureter necrosis caused by ischemia. Reported incidence is between 1.5% and 8.9%.[48] An attempt should be made to manage it conservatively with bladder catheterization, double-J stent placement if not previously stented, and drainage of urine in perinephric space with a percutaneous drain. Unless there is complete disruption of the ureteroneocystostomy, these maneuvers may work to seal the leak. If they do not work, open surgical techniques, as mentioned earlier for ureteral stenosis, will be needed.

SUMMARY

Kidney transplantation is an evolving field with many advances being made to diminish organ-shortage constraints and decrease waiting times for accessing lifesaving transplants. The current landscape of kidney transplantation aims to equitably increase access to organs by broadening the donor pool, improving allocation algorithms, and decreasing organ discard from deceased donors. Careful selection of transplant recipients is important to ensure maximal benefit from this limited resource. Success of a kidney transplant depends on careful selection of a donor organ and suitable recipient, as well as meticulous surgical technique to prevent postoperative surgical complications.

Surgical Considerations
Postoperative Management
Complications and Their Treatment
Immunosuppression
Living Donor Liver Transplantation, Including Donor Selection
- Donor
- Recipient

Pediatric Liver Transplantation
- New Technologies, Treatment Paradigms and Advances

HISTORY

More than 90% of patients receiving a liver transplant in the United States will be alive 1 year after the surgery, and almost 88% will be alive after 3 years.[1] This extraordinary achievement arose as a result of the synthesis of a myriad of discoveries in disparate fields. Liver transplantation represents a triumph of scientific achievement, collaboration, and teamwork.

Seminal discoveries instrumental in developing transplantation trace back more than 100 years. These include the technical achievements of Alexis Carrel in creating vascular anastomoses in the first decade of the 20th century. While performing research on skin grafting for soldiers in World War II in the early 1940s, Sir Peter Medawar discovered graft loss was due to immunologic factors, specifically cell-mediated immunity.[2] His subsequent studies established the efficacy of steroids to protect against graft injury.[3] In 1952, the chemists Gertrude Eillion and George Hitchings at Burroughs-Wellcome synthesized azathioprine and 6-mercaptopurine, which would become cornerstones of early immunosuppressive therapy. In 1954, Joseph Murray proved transplantation could be successful by performing a renal transplant using an identical twin as a donor.[4] In 1959, Dr. Murray went on to demonstrate the feasibility of transplantation across immunologic barriers using total body irradiation to suppress the immune system.[5] All of these investigators earned a Nobel Prize in recognition of their accomplishments.

Despite these advancements allowing limited success for kidney transplantation, early attempts at human liver transplantation were marked by failure (expertly chronicled in the book *The Puzzle People* by Thomas Starzl).[6] Technical complexities of the operation, coagulopathy, metabolic derangements, and poor understanding of the immunologic basis of graft loss conspired to produce poor outcomes. The first attempt at human liver transplantation in 1963 by Dr. Starzl failed, as did subsequent attempts in Berlin, Boston, and Paris. Things looked so grim that Starzl himself placed a 3-year moratorium on liver transplantation, returning exclusively to the lab to determine how to best move forward.[6]

With advances in technique and immunosuppression, limited success was achieved. In the 1970s, Starzl reported 1-year survival rates around 30%.[7] Nearly two decades after the first liver transplant was attempted, Jean Borel discovered that cyclosporine, initially investigated as an antifungal agent, had immunosuppressive properties.[8] This discovery ushered in the modern era of liver transplantation as cyclosporine became the mainstay of antirejection therapy.

As outcomes improved, attention turned toward maximizing the number of available donors. In 1989, Mies and colleagues[9] in Brazil described two cases of liver transplantation from live adult donors into children, although neither achieved long-term survival. The first generally accepted successful living donor liver transplantation (LDLT) in a pediatric recipient was performed by Strong and colleagues.[10] A Japanese group led by Koichi Tanaka produced excellent outcomes using these techniques and established the reliability of this approach.[11] Approximately 10 years later, the first adult-to-adult LDLT using the left lobe was performed by Hashikura and colleagues.[12]

Other efforts to expand the donor pool include the use of grafts produced after circulatory determination of death and grafts with higher than previously accepted fibrosis or fat content for selected recipients. To this end, the past 10 years have seen a rapid increase in techniques that allow transplantation of more marginal grafts. These include ex vivo normothermic and hypothermic machine perfusion of any marginal grafts as well as normothermic regional perfusion of circulatory death grafts.

INDICATIONS

Indications for adult liver transplantation fall into two main categories: (1) symptomatic liver failure and (2) select liver tumors with tumor location or accompanying liver disease preventing proper oncologic resection. Disease states causing liver failure that may be successfully treated with transplant include noncholestatic and cholestatic cirrhosis (Box 53.1), cancer, fulminant hepatic failure, metabolic diseases, and biliary atresia as well as a relatively rare mix of other causes, including Budd-Chiari syndrome, hyperalimentation-induced liver disease, large adenomas, and polycystic liver disease. With the advent of effective antiviral therapy for hepatitis C, the most common reason patients are listed for liver transplantation is alcoholic liver disease, followed by metabolic-associated steatohepatitis (MASH), which rose dramatically in the late 2010s, followed by hepatitis C.

Noncholestatic Cirrhosis

The common theme in these diseases is hepatocyte injury. Although the liver has a unique potential to regenerate, over time, chronic hepatocyte injury results in stellate cell activation, leading to widespread collagen deposition. This process disrupts the unique liver microstructure that allows low-pressure portal blood flow, nutrient exchange, and bile secretion. This in turn leads to portal hypertension and associated varices and ascites. As hepatocyte synthetic and excretory function fails, coagulopathy, jaundice, hypoalbuminemia, fatigue, pruritus, and encephalopathy may occur. Additional complications, the development of which is poorly understood, include hepatorenal syndrome, hepatopulmonary syndrome, and portopulmonary hypertension. The term *noncholestatic* reflects that the primary injury is to the hepatocytes and not the bile ducts, even though patients can and often do present with jaundice.

Alcoholic

Alcoholic liver disease encompasses steatohepatitis, alcoholic cirrhosis, and alcoholic hepatitis.[13] The absolute number of patients listed with this diagnosis is growing, and chronic alcohol ingestion remains the most common indication for liver transplantation, responsible for approximately 39% of all listings.[1] Ingestion of 30 g of alcohol per day seems to be a relevant threshold and will cause chronic liver damage in approximately 6% of people; risk increases with increasing use.[14] Screening for alcoholic liver disease (ALD) is recommended with biochemical testing and liver ultrasonography in any patients meeting harmful use criteria. These include greater than 3 drinks per day in males and greater than 2 drinks per day in females for a duration greater than 1 year. Not all patients meeting these criteria will have acute or chronic liver disease, but screening evaluation should still take place if history is elicited.

Toxicity of ethanol is incompletely understood but likely depends on conversion to acetaldehyde via alcohol dehydrogenase, catalase, or cytochrome P450. Over time, pericentral fibrosis progresses to panlobar fibrosis with associated manifestations of cirrhosis. The ratio of aspartate aminotransferase (AST) to alanine aminotransferase (ALT) is typically greater than 2, and transaminase elevation tends to be relatively mild (<500).

Alcoholic hepatitis is a subset of alcohol-associated liver disease that occurs in patients with a long history of alcohol use who present with an acute inflammatory syndrome with a bilirubin of greater than 3.0 mg/dL. Episodes can be self-limited or lead to complete liver failure. This diagnosis is increasingly common as an indication for liver transplantation.

Historically, decisions regarding whether to list a patient with ALD for transplantation depended on a period of sobriety before transplant, typically 6 months, because of concern for recidivism and injury to the transplanted liver. Policies vary by center, but in general, these guidelines have been relaxed over time because there is evidence from European studies to suggest good outcomes in patients transplanted for alcoholic hepatitis with shorter-duration abstinence of periods as long as 2 weeks.[15] Current practice guidance from the American Association for the Study of Liver Diseases on alcohol-associated liver disease recommends referral for transplant if the model for end-stage liver disease (MELD) is greater than 20.[16] Such patients with no improvement in liver disease after a 6-month period of abstinence are recommended to undergo liver transplantation evaluation if the MELD score in greater than 17.

BOX 53.1 Disease States Causing Liver Failure That May Be Successfully Treated With Transplant

Noncholestatic Cirrhosis
- Alcoholic
- Metabolic-associated fatty liver disease
- Hepatitis C
- Cryptogenic cirrhosis
- Autoimmune cirrhosis
- Hepatitis B
- Drug or exposure induced

Cholestatic Cirrhosis
- Primary biliary cirrhosis (PBC)
- Primary sclerosing cholangitis (PSC)
- Caroli disease
- Choledochal cyst

Metabolic-Associated Fatty Liver Disease

Metabolic-associated fatty liver disease (MAFLD) is a recently coined term to describe a complex and heterogeneous disease phenotype with several causes. This shift represents our increasing understanding of the disease as one influenced by a panoply of factors, such as age, sex, ethnicity, environmental factors, diet, genetic predisposition, an individual's microbiota, and even their alcohol intake (Fig. 53.1).[17] The change in terminology also reflects the patient perspective because the term *nonalcoholic* can make light of the disease process and even assign blame for the patient's condition as well as its treatment.

The drivers of MAFLD for an individual will vary greatly based on factors present, and thus, the ways to address and study the disease also vary. This is among several reasons for the nomenclature change. MAFLD reflects a spectrum of disease, ranging from mild to moderate hepatic steatosis to the inflammatory condition known as *metabolic-associated steatohepatitis* (MASH; formerly known as *nonalcoholic steatohepatitis* [NASH]) and end-stage liver cirrhosis. It is important to recognize the full spectrum of disease because pathology such as hepatocellular carcinoma has been observed even in patients with moderate steatosis without MASH or cirrhosis.

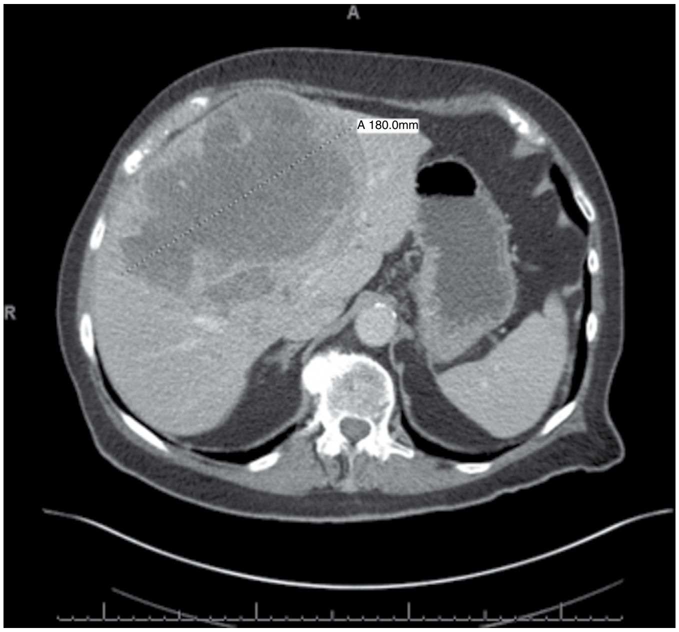

FIGURE 53.1 Heterogeneity of metabolic-associated fatty liver disease.

This spectrum of disease is more common in Western nations, affecting over 1 billion people worldwide. The prevalence of MAFLD worldwide is about 25%, with MASH prevalence worldwide being around 4% to 6%. In America, approximately 20% to 30% of adults meet criteria for some form of MAFLD, although only about 4% of patients with steatosis progress to cirrhosis. Still, MAFLD must be taken seriously because roughly 20% of patients progressing from hepatic steatosis to MASH will go on to develop liver cirrhosis over their lifetime.[18] MASH is now the second most common indication for liver transplantation in the United States. Biopsy in MASH demonstrates hepatocyte steatosis, ballooning degeneration, and lobular inflammation, most commonly in zone 3. Over time, the inflammation can progress to fibrosis, cirrhosis, and liver failure, leading to the need for liver transplantation. Before end-stage cirrhosis and liver failure, lower levels of hepatic steatosis can be reversible in some patients with diet and lifestyle modification as well as control of metabolic syndrome–associated comorbidities (diabetes, hyperlipidemia, and hypertension). MASH, however, has been historically difficult to treat. Very recent advances in the understanding of MASH pathophysiology have led to the development of Resmetirom, a thyroid hormone receptor β-selective agonist. This first-in-class treatment demonstrated biopsy improvement of MASH and MAFLD activity as well as low-density lipoprotein cholesterol levels in the treatment group compared with placebo in a phase III study and was FDA approved in March 2024.[19]

The growing incidence of MAFLD in the Western world has also begun to affect liver donation, with an increasing number of potential donors being unsuitable because of higher levels of steatosis and early MASH development on recovery biopsy.

Hepatitis C

In 2016, Bartenschlager, Rice, and Sofia were awarded the Lasker-DeBakey Clinical Medical Research Award for efforts instrumental in developing effective therapies for hepatitis C.[20] Their work, and that of many others, revolutionized the care and treatment of patients with advanced liver disease in two fundamental ways. First, it greatly reduced the burden of hepatitis C and the number of patients being listed with this diagnosis, and second, it allowed the use of organs from donors with hepatitis C, significantly increasing the organ supply. As a result, hepatitis C has gone from the most common to the third most common indication for liver transplantation in the United States, a truly remarkable achievement.

Patients who present with advanced cirrhosis should be considered for liver transplantation consistent with usual clinical indications. Patients with mild disease should be treated with the end goal of sustained virologic response (SVR), defined as undetectable hepatitis C virus (HCV) RNA in the serum or plasma either 12 weeks or 24 weeks after the end of therapy. Those achieving SVR may delay or arrest further disease progression and, in some cases, reverse fibrosis.[21] In patients with advanced disease, the decision to treat is individualized to the patient. Depending on the level of fibrosis, all patients, including those achieving SVR, must have regular posttreatment hepatocellular carcinoma (HCC) surveillance (as frequent as every 6 months) because the risk of cancer development remains.

Cryptogenic

Cryptogenic cirrhosis remains an ambiguous cause of liver disease and is a diagnosis of exclusion. Up to 30% of liver cirrhosis is due to cryptogenic cirrhosis as well as up to 10% of liver transplants. Ongoing scholarship suggests that many patients with cryptogenic cirrhosis share a lot of comorbidities with those diagnosed with MASH-related cirrhosis. Histopathologic evidence also demonstrates that during the natural progression of MASH, steatosis can disappear, leaving extensive fibrosis seen in cirrhosis without clear evidence of the preceding steatohepatitis. This has led many to believe most of what we consider cryptogenic cirrhosis is actually "burnout-stage" advanced MASH cirrhosis. Still, there are some groups finding distinct differences between cohorts of patients with cryptogenic cirrhosis and MASH cirrhosis, and debate continues on whether it should be its own pathologic entity.[22,23] The diagnosis, treatment, and decision-making remain similar to patients with MASH.

Autoimmune

Autoimmune hepatitis is an inflammatory disease of the liver with poorly understood etiology. Some accepted hypotheses include loss of immunologic tolerance against hepatocytes by the environment in some genetically predisposed individuals (possessing human leukocyte antigen [HLA]-DR3 and HLA-DR4 alleles) as well as possible molecular mimicry. It occurs mostly in females (75%), with a bimodal age distribution of patients in their 20s and in their 50s to 60s, although it is reported in both sexes and all age groups, including pediatric populations.[24] The course can be self-limited or recurrent, leading to chronic liver disease and cirrhosis requiring transplantation. Diagnosis is typically one of exclusion. Characteristic findings on laboratory evaluation include high elevations in AST and ALT, lesser elevations in alkaline phosphatase, and elevated gamma globulins. Antinuclear and anti–smooth muscle antibodies as well as IgG are often elevated. Histologic findings include a mononuclear cell infiltrate primarily in the portal regions, and piecemeal necrosis may be present at the periportal region. Most patients will have ductal injury, and plasma cell infiltrates are common. In the initial stages of the disease, fibrosis may be absent. As the disease progresses, fibrosis occurs and may develop into cirrhosis. Transplantation should be considered for patients who develop cirrhosis.

Hepatitis B

Approximately 3.8% of the world population has been exposed to hepatitis B, and nearly 296 million are chronic carriers,[25] making hepatitis B a major public health problem. Acute infection with hepatitis B is subclinical in 70% of patients. Approximately 30% will develop jaundice. Less than 1% will develop fulminant hepatic failure. These patients should be considered for emergent liver transplantation. In patients who develop chronic infection, progression to cirrhosis is influenced by the age of onset. For perinatal acquired infection, 90% will progress to chronic infection, with rates decreasing as the age of transmission increases.[25]

Up through the late 1990s, transplantation for patients with hepatitis B produced poor outcomes as a result of disease recurrence. This changed with the discovery of lamivudine, which, in combination with hepatitis B immunoglobulin, allowed successful transplantation of these patients. In current practice, patients with hepatitis B routinely receive liver transplants, and donors with hepatitis B can be used with appropriate antiviral therapy.

Cholestatic Liver Disease

The common thread in this group of diseases is chronic biliary damage. As ducts become injured, bile stasis occurs, leading to infection and a vicious cycle of damage, inflammation, and recurrent infection. Pruritis can be debilitating. Recurrent cholangitis may produce the classic Charcot triad of jaundice, fever, and right upper quadrant pain. Ongoing biliary damage predisposes the patient to the development of cholangiocarcinoma, especially in patients with primary sclerosing cholangitis (PSC).

Primary Biliary Cholangitis

Primary biliary cholangitis is an autoimmune disease in which inflammatory injury to the bile ducts results in cholestatic liver disease. Granulomatous destruction of the intralobar ducts resulting from loss of immune tolerance to biliary epithelial cells causes obstruction and jaundice.[26] Patients often suffer from jaundice and pruritis. Laboratory evaluation typically reveals elevated alkaline phosphatase, and positive antimitochondrial antibodies are often present. History often reveals fatigue and pruritis, with physical exam showing jaundice and xanthomata. Osteoporosis commonly develops. Positive antimitochondrial antibodies are the hallmark of the disease. The mainstay first-line treatment is the use of ursodeoxycholic acid, with several mechanisms of action suggested. Roughly 40% of patients do not respond to this therapy and will eventually require transplantation at higher rates than responders to initial therapy.

Primary Sclerosing Cholangitis

Patients with PSC develop fibrosis of the intrahepatic and/or extrahepatic biliary tree, leading to inflammation. The disease is more common in males. Diffuse structuring leads to jaundice, pruritis, fibrosis, recurrent biliary sepsis, and liver failure. Many patients with PSC also have a history of inflammatory bowel disease. These patients are at high risk for cholangiocarcinoma and require careful screening. Laboratory evaluation most commonly shows elevated alkaline phosphatase. In addition, gammaglobulin, serum immunoglobulin M levels, atypical perinuclear antineutrophil cytoplasmic antibodies, HLA DRw52a, antinuclear, anti–smooth muscle, anticardiolipin, thyroperoxidase, and rheumatoid factor may be elevated and can provide clues to the diagnosis. Antimitochondrial antibodies are generally negative in contrast to primary biliary cholangitis.

Patients with PSC carry a significant risk of cholangiocarcinoma of 13%. With the onset of cholangiocarcinoma, carbohydrate antigen 19-9 (CA 19-9) levels typically rise and should be followed serially.

Caroli Disease

Caroli disease is a poorly understood congenital disorder of the large intrahepatic bile ducts. Most commonly, the disease is transmitted in an autosomal recessive fashion associated with polycystic renal disease. When associated with congenital hepatic fibrosis, the term *Caroli syndrome* is used. Like PSC, stasis, recurrent infection, and ongoing fibrosis lead to liver failure in some patients, although the severity of disease is variable. Patients are at risk for the development of cholangiocarcinoma.

Acute Liver Failure

Acute liver failure (ALF) is a clinical syndrome of liver injury (elevated transaminases), hepatic encephalopathy, and coagulopathy (elevated prothrombin time [PT]/international normalized ratio [INR]) in patients without preexisting liver disease. Terminology can be confusing. In general, *fulminant liver failure, acute hepatic necrosis, fulminant hepatic necrosis,* or *fulminant hepatitis* can refer to the same clinical syndrome. Importantly, the presence of encephalopathy is required for the diagnosis and for listing in the most urgent category for liver transplant, a status 1A designation.

ALF can be further divided based on the duration between onset of symptoms and encephalopathy. Hyperacute liver failure occurs within 7 days of symptom onset; acute, from 7 to 21 days; and subacute, between 21 days and 26 weeks. The shorter the duration of symptoms, the more common it is for patients to develop cerebral edema. In contrast, patients with disease of longer duration more commonly present with portal hypertension.

The most common causes of ALF are given in Box 53.2, with acetaminophen overdose being the most common cause.

Patients with ALF present with challenging management decisions, centered around determining who needs a transplant and who will improve with supportive management. Although successful transplantation is associated with excellent survival (84% 1-year survival in the United States), it is still inferior to the survival rates of patients who spontaneously recover.[27] Contrarily, failure to list and perform a transplant in a patient who needs one will result in death. This is made more challenging by the need for an expeditious workup and, if needed, listing for transplantation. The challenge is typified by patients with acetaminophen overdose, who tend to be young but may have a history of multiple suicide attempts or poor social support, leading to challenges in treatment decision-making. Hospital mortality for patients with ALF can be predicted by the MELD system or the King's College Criteria, with evidence suggesting more

BOX 53.2 Common Causes of Acute Liver Failure

- Autoimmune
- Ischemia
- Wilson disease

accurate mortality prediction among acetaminophen-associated ALF with the King's College Criteria.

Progression of hepatic encephalopathy to stage II can be used as a guideline to move forward with transplant, although this differs among transplant centers. More precise determination in these patients again uses the King's College Criteria.[28] In a patient with acetaminophen overdose, arterial pH less than 7.3 after resuscitation or high PT, creatinine, and grade III or IV encephalopathy suggest need for transplant. Use of serial computed tomography (CT) scans or an intracranial pressure monitor (bolt) can help guide therapy and, importantly, the decision to proceed with transplantation.

Malignant Neoplasms

Hepatocellular Cancer

In 2022 approximately 16% of transplants performed in the United States were performed for HCC as the primary indication.[1]

Initial efforts in performing liver transplantation for HCC produced dismal results, with very high recurrence rates. Over time, it became apparent that early-stage lesions did quite well; clinical evidence began to demonstrate the correlation between initial tumor size and number, risk of micrometastasis, and recurrence. The best set of clinical criteria based on this relationship was published by a group in Milan, eponymously defined as the *Milan Criteria*.[29] These early-stage lesions have equivalent survival to nonmalignant indications for transplantation. To prioritize these patients for transplant to receive a graft before the development of metastatic disease, exception points can be granted for patients with up to three lesions, each between 1 and 3 cm in diameter, or one lesion 2 to 5 cm in diameter. It is recommended that patients with HCC be managed in a multidisciplinary setting with the use of locoregional therapies, including transarterial chemoembolization, radiofrequency ablation, and radioembolization using Y90, to "downstage" patients into "within" Milan Criteria, with excellent results. Many guidelines are available for surgical management of HCC patients, including liver transplantation, with one of the more widely used and modified being the Barcelona Clinic Liver Cancer staging system (BCLC). This system factors tumor size and number, patient performance status, and liver function to classify patients into stages that correlate with treatment algorithms depending on group.[30] Recent modifications recognize the poor prognosis carried by high α-fetoprotein levels and require special exception point applications for these patients.

Many patients with hepatocellular cancer have significant underlying fibrosis or cirrhosis. The primary treatment modality for HCC is surgical resection. The determination must be made as to whether the underlying liver disease will allow successful resection. In general, 30% of the liver must be preserved to ensure adequate synthetic function; however, in the setting of significant liver disease, this proportion may be as high as 40% to 50% and can be prohibitive of resection depending, again, on tumor size and location. Severe portal hypertension with varices, significant ascites, debilitation, malnutrition, and encephalopathy are all contraindications to resection. In addition, the location of the lesion may also make resection impossible. Lesions adjacent to the confluence of major vascular or biliary structures may not allow surgical options. In this case, transplantation is the preferred treatment.

Chemotherapy and other locoregional therapies may be employed to halt the progression of disease while patients remain on the wait list.

Cholangiocarcinoma

Cholangiocarcinoma is a highly lethal primary liver lesion with poor long-term survival. In patients with perihilar lesions who are not surgical candidates, 3-year survival is nearly 0%. This is due to the aggressive nature of cholangiocarcinoma, with micrometastasis being present in most patients with visible lesions on imaging. Early reports from the Mayo Clinic demonstrated that chemoradiation protocols followed by liver transplantation provided good long-term survival for patients with early-stage hilar lesions.[31] Still today, few centers have adopted any criteria for transplanting patients with cholangiocarcinoma because all but the most carefully selected patients experience a survival benefit. Despite this benefit, 1- and 3-year disease recurrence rates are very high, leading some countries, such as Japan and Germany, to not offer transplantation as a therapeutic option. Centers listing and transplanting these patients report that these patients have been carefully selected and show equivalent survival to patients who undergo liver resection. There is still wide practice variation, with not all centers including radiation therapy and some choosing up-front transplantation for the smallest perihilar tumors. A key principle is the need to obtain a negative margin either with transplantation or resection.

Other

Budd-Chiari Syndrome

Budd-Chiari syndrome is a rare condition that occurs when hepatic venous outflow is occluded, typically due to thrombosis of the hepatic veins or vena cava at the level of the hepatic veins. It can also occur as a result of extrinsic compression. Presentation is variable and can be divided into acute, subacute, and chronic. Approximately 5% of patients will present with ALF. In these patients, ascites and pain are more common, whereas patients with chronic obstruction more frequently present with portal hypertension. An underlying hypercoagulable or other reason is identified in about 75% of patients[32] and should be actively sought with a hypercoagulable workup and imaging to look for masses (Fig. 53.2).[33]

In early stages, side-to-side portacaval shunt decompresses the liver and can provide excellent long-term survival. In patients with established fibrosis or cirrhosis, liver transplantation should

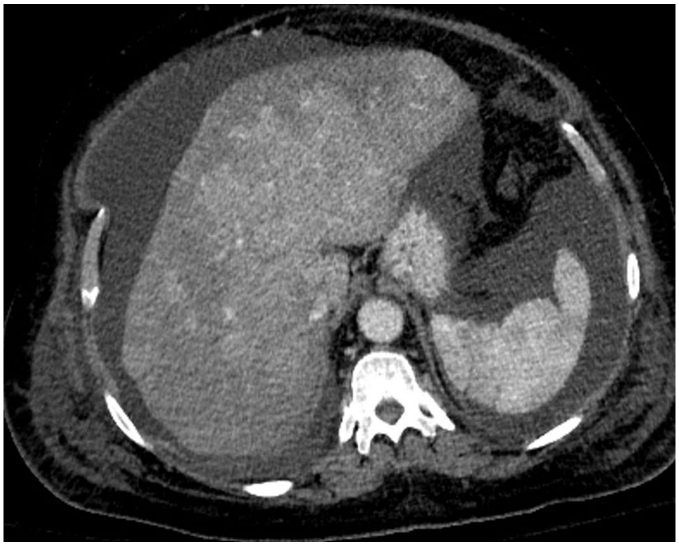

FIGURE 53.2 Budd-Chiari syndrome.

be considered. Operative planning must consider suitable outflow options, particularly side-to-side cavocavostomy.

Rare Causes of Liver Failure That Can Be Addressed With Liver Transplantation

Total Parenteral Nutrition/Hyperalimentation-Induced Liver Disease

In patients with short bowel syndrome or intestinal failure, liver failure can follow for reasons that are not well understood. In these patients, combined liver/intestinal transplant can be lifesaving.

Polycystic Liver Disease

In rare cases, patients with polycystic liver disease can present with debilitating pain, intestinal obstruction, malnutrition, hemorrhage, or liver failure. For these patients, liver transplantation may be indicated.

Hepatic Adenoma

Patients with large, unresectable hepatic adenomas may present with pain or bleeding and carry increased risk of malignancy. Transplant is indicated for symptomatic, large, unresectable lesions.

Metastatic Cancer

Certain types of metastatic disease can be treated with transplantation, including neuroendocrine tumors and unresectable colorectal liver metastases. Liver transplantation for metastatic cancers, including colorectal cancer, had been tried before, with demonstrated abysmal outcomes in the 1980s. The practice is slowly returning with better selection criteria for recipients. There has been growing literature on transplantation for unresectable colorectal liver metastases, with the initial study of 21 patients with unresectable colorectal liver metastases from Oslo, Norway (SECA-I), showing a 60% 5-year survival rate after liver transplantation. This trial was recently followed up in a 2020 report from the same group (SECA-II) demonstrating a 5-year survival of 83% and a 5-year disease-free survival of 35% in a highly selected cohort.[34] Although still not as common, more centers have begun to develop selection criteria based on these reports for the transplantation of unresectable colorectal liver metastases. This remains a controversial indication, but as will be discussed in a subsequent section, a new field of "transplant oncology" is emerging to revisit the idea of expanding liver transplant indication to many cancer types.

Hemangioendothelioma

Hemangioendothelioma is a slow-growing and rare malignancy. In the case of unresectable disease, transplant can provide excellent outcomes.

Wilson Disease

Occurring at a frequency of 1 in 30,000, Wilson disease is an autosomal recessive disease of copper transport. Over time, copper accumulation leads to cirrhosis. A small subgroup of patients will present with liver failure, which is generally an acute presentation on the background of undiagnosed cirrhosis. These patients benefit from transplant and have good long-term survival.

CONTRAINDICATIONS

As techniques and technologies for liver transplantation improved, the number of patients who could benefit increased at a rate that outpaced organ availability. To be good stewards of the limited resource, the decision-making around listing patients for liver transplant is more complex than in other areas of surgery. Contraindications are based on whether the patient can survive the operation and whether they can achieve long-term survival, including whether they can properly care for the organ.

Patients with advanced cardiac disease are usually excluded from consideration for transplant. Severe valvular disease can make intraoperative management prohibitively difficult. Hypotension may occur as a result of rapidly shifting intravascular volume with significant hemorrhage or clamping of major vasculature. This can also lead to life-threatening arrhythmias. A particularly difficult problem is pulmonary hypertension, which may result in unrecoverable right heart failure on reperfusion of the new liver. Patients with coronary heart disease are at risk for intraoperative myocardial infarction and may have accelerated progression of atherosclerosis as a result of immunosuppression after transplant.

Similarly, patients with severe respiratory conditions are generally not candidates for liver transplantation. Intraoperative hypoxia may be uncorrectable, and long-term outcomes are poor. Portopulmonary hypertension uncorrectable to less than 50 mm Hg is generally considered a contraindication, as is hepatopulmonary syndrome if the PaO_2 cannot be corrected on 100% oxygen.

Other contraindications include irreversible neurologic impairment. In the setting of encephalopathy, this can be difficult to determine. A careful history is needed to exclude chronic, progressive causes. Infection must be carefully considered but, in many cases, is not an absolute contraindication. For example, in patients with PSC and liver abscesses, liver excision may be the only way to eradicate the infection. Uncontrolled sepsis or other infection that will not be cured by the transplant is a relative contraindication. In most cases, extrahepatic cancer is a contraindication for transplant. Recent cancer may require a waiting period. The Israel Penn International Transplant Tumor Registry maintains a database that can provide guidance around waiting times needed for different types of cancer. Patients with human immunodeficiency virus (HIV), previously thought to be an absolute contraindication to transplant, can undergo successful transplantation. A 2013 congressional act, the HIV Organ Policy Equity (HOPE) Act, enabled transplantation from HIV-positive donor to HIV-positive recipient to take place under research protocols reviewable by the US Department of Health and Human Services. A recent multicenter prospective report in 2022 demonstrated the best outcomes to date, with 45 HIV-positive recipients (R+) without AIDS or evidence of opportunistic infection receiving either HIV-positive or HIV-negative donor livers (D– or D+). Compared with HIV-positive recipients who received livers from HIV-negative donors (D–/R+), HIV-positive recipients receiving livers from HIV-positive donors (D+/R+) had excellent 1-year survival (83.3% vs. 100%; $p = 0.04$), with no difference in rejection rates (10.8% vs. 18.2%; $p > 0.05$).[35] Such results merit further investigation but are promising for a future where HIV status will no longer be a relative contraindication, similar to HCV.

The transplant community generally feels that the ability to take care of the graft depends on adequate social and financial support and resources, so lack of this resource is an absolute contraindication to transplantation, although recent work suggests this may be a disadvantage to certain groups of patients.[36]

Active alcohol use is considered a contraindication for transplant, although selected centers will perform transplants in these patients, and in fact, the number of these transplants is increasing rapidly.[15] Liver transplant programs generally include social, psychiatric, and finance specialists to help sort out relevant issues.

Advances in surgical technique have made exclusion of patients for anatomic reasons very rare in experienced centers. Methods for dealing with difficult anatomy are discussed in the section on surgical considerations.

MELD AND ALLOCATION

Originally developed to predict 3-month mortality in patients after transjugular portosystemic shunt placement, the MELD was also found to accurately predict mortality in patients waitlisted for transplant. Currently, the MELD score (now on its third iteration) determines priority for liver transplantation. A great success of the system was in creating objective criteria (laboratory results) that were not subject to interpretation by individual centers, as was the case for grading of hepatic encephalopathy under the Child-Turcotte-Pugh system. In its original formulation in 2003, it was based on serum creatinine, INR, and bilirubin. Serum sodium was subsequently added to improve the predictive value of the score for those with a regular MELD score greater than 11. The latest iteration of the model (3.0) includes the variables of female sex and serum albumin as well as interaction terms between variables to correct previous disparities among females as well as create a more predictive model based on contemporary data.[37] The current calculation is included in Box 53.3. When a donor liver becomes available, a list of patients eligible to receive the transplant is generated, ranked by MELD score. The liver is offered sequentially to each person on the list until it is accepted.

Status 1 patients suffer from fulminant liver failure, with expected death on the order of days. These patients are prioritized above patients with MELD scores.

Although MELD is recognized as a good predictor of mortality, there are certain conditions thought to carry higher mortality than the MELD score would suggest. In particular, patients with hepatocellular cancer can be cured with liver transplantation, but many have low MELD scores because of preserved liver function and would likely not come to transplant before disease progression. For these patients, additional points are given, termed *exception points,* to reflect the desire of the community to prioritize them. Prioritization algorithms are reviewed and adjusted regularly to ensure equity among all waitlisted patients. Additional diagnoses generally accepted for additional points are listed in Boxes 53.4 and 53.5. If patients do not fit into these categories, a review board exists to consider special cases.

How organs are distributed across the country is a distinct question regarding which patients in a group receive priority for the transplant offer. This complex question is one of the most hotly debated in the transplant community. Within this decision resides the intersection of ethical principles of justice, utility, and fairness, as well as public preferences, resource utilization, and disparities in access and outcomes of care resulting from socioeconomic factors.[38] In February 2020, liver allocation policy radically changed from donation service areas to “acuity circles” in an effort to reduce disparities based on geography that resulted in widely different median MELD scores at time of transplant depending on geographic location.[39] In practice, this created concentric donation circles around liver donor hospitals rather than offering livers based on where the recipient lived, ranging from 150 to 500 nautical miles. For example, when a donor offer becomes available at a hospital, that offer will be made first to any recipients considered status 1A (imminent risk of death within less than 1 week) within a 500-nautical-mile radius of the donor hospital. If no such recipient is found, it is first offered to any high-MELD recipients within 150 nautical miles, then any similar MELD recipients within 250 nautical miles, followed by 500 nautical miles until a high-MELD recipient is found. If no high-MELD recipient is found, the process repeats, with progressively lower-MELD recipients within 150, 250, and then 500 nautical miles being offered until a recipient match is found. This change to allocation policy was met with skepticism, with some believing it would lead to the net exportation of liver grafts from more resource-poor geographic areas. Many studies have been published since implementation, but more time is needed to determine the ultimate impact of the policy change as well as brainstorm improved policies.

BOX 53.3 Current Calculation for the Model for End-Stage Liver Disease (MELD 3.0) Score

$$\text{MELD} = 1.33*(\text{Female}) + 4.56*\ln(\text{Serum bilirubin}) + 0.82*(137 - \text{Sodium}) - 0.24*(137 - \text{Sodium})*\ln(\text{Serum bilirubin}) + 9.09*\ln(\text{INR}) + 11.14*\ln(\text{Serum creatinine}) + 1.85*(3.5 - \text{Serum albumin}) - 1.83*(3.5 - \text{Serum albumin})*\ln(\text{Serum creatinine}) + 6$$, Rounded to the nearest integer

INR, International normalized ratio.

BOX 53.4 Common Indications for Exception Points for Liver Transplant

- Hepatocellular carcinoma
- Hepatopulmonary syndrome
- Portopulmonary hypertension (provided the mean arterial pressure can be maintained at <35 mm Hg with treatment)
- Familial amyloid polyneuropathy
- Primary hyperoxaluria
- Cystic fibrosis
- Hilar cholangiocarcinoma
- Hepatic artery thrombosis (occurring within 14 days of liver transplantation but not meeting criteria for status 1A)

BOX 53.5 Diagnoses That May Be Appropriate for Exception Points

- Recurrent cholangitis in patients with primary sclerosing cholangitis who are on antibiotic suppressive therapy or require repeated biliary interventions
- Refractory ascites
- Refractory hepatic encephalopathy
- Refractory variceal hemorrhage
- Portal hypertensive gastropathy leading to chronic blood loss
- Intractable pruritus in a patient with primary biliary cirrhosis

In March 2023 the US Department of Health and Human Services announced plans to overhaul and reform the United Network for Organ Sharing (UNOS) in response to growing criticism of declining transplant outcomes and inefficient organ utilization rates. This led to the signing of the Securing the US Organ Procurement and Transplantation Network Act in September 2023, which promises to break up UNOS and award multiple contracts for organ administration networks. This will allow broader eligibility and more transparency in transplant allocations, including better performance-based metrics. Finally, whether and how to incorporate performance of local organ procurement organizations will be included for potential change as the landscape of American transplantation rapidly changes. Allocation thus remains a complex and hotly contested topic, with change anticipated in the coming years.

DONOR SELECTION

The ideal liver donor is young, healthy, and thin, with normal liver function tests and no history of liver disease or risk factors for infectious disease. The patient is pronounced brain dead and, with normal hemodynamics, is taken semielectively for the donation procedure. This "perfect" scenario is quite rare, however, and each deviation from these characteristics carries quantifiable risks. It is critical to consider that the risk of accepting any individual donor must be balanced with the risk of the potential recipient declining the liver and dying before receiving the next offer. From a public health standpoint, use of livers with high risk is, in general, preferable to not using the liver, given the number of waiting-list deaths.

Older donors carry additional risk of short- and long-term graft loss, and older age is an independent risk factor for mortality. Still, outcomes with older donors are very good.[40]

Donors with significant health problems need to be considered on a case-by-case basis. In general, disease in other organs should not be a contraindication to use of the liver. A notable exception is cancer, but this still must be considered on a case-by-case basis. Severe atherosclerosis can affect the hepatic artery, and this must be assessed at the time of donation.

Livers from patients who are obese may have MAFLD with or without MASH. In general, livers with more than 60% steatosis or with significant fibrosis for any reason should be used with caution, if at all, for only the most robust recipients. Bridging portal fibrosis and cirrhosis are typically contraindications for using any donor liver.

Interestingly, ongoing infection in the donor is not an absolute contraindication for use of the organ. Suspicion of viral etiology for the donor death, however, is typically an absolute contraindication for the use of any organs. Spread of the virus to immunosuppressed recipients can cause multiple deaths. Patients with risk factors for infection, such as intravenous drug abuse, carry a small risk of transmission of disease even though nucleic acid testing is routinely performed and is very sensitive for hepatitis C and HIV. The use of hepatitis C–infected donors is becoming routine given the success of specific antiviral therapy, and there is already some early evidence to suggest acceptable outcomes of HIV-positive donors only for HIV-positive recipients.

The standard liver donation comes from a deceased patient declared dead by brain death criteria. Brain death is declared by the patient's treatment team, independent of and before any family members being approached by a transplant services team for donation consent. Recipients of these grafts tend to have the best outcomes, although not as good as those of living donation, which is covered later in this chapter.[1] A class of organs can also be procured from donors declared dead based on circulatory criteria. These are termed *donation after circulatory death (DCD) organs*. In this case, after determination that the patient experienced a devastating, nonsurvivable injury and that the patient wishes to donate, support measures are withdrawn, and the patient is allowed to progress to death. Once the patient is declared dead by cessation of heartbeat, a "hands-off" period ranging from 5 minutes (in the United States) to as long as 15 to 20 minutes in some European countries is observed in case of autoresuscitation. A physician, typically the intensivist team, must confirm lack of pulse and heartbeat before the surgical team can proceed. A rapid perfusion technique with organ removal is performed by quickly opening the abdomen and cannulating the donor aorta to initiate a cold flush of preservation solution. DCD donors are a significant source of organs for transplant, with excellent outcomes in selected hands, and their use has increased over several years.[41] These organs are not without risk, however, because of both warm and cold ischemia. Each hour of cold ischemia increases risk of graft failure for DCD organs, and many donor comorbidities, such as macrosteatosis, have higher rates of graft loss in DCD organs than donation after brain death (DBD) donors. Ischemic cholangiopathy, a diffuse structuring disease, also occurs with more frequency in these donors compared with DBD livers, and this complication can, in some cases, require retransplantation.

PREOPERATIVE EVALUATION

Evaluation of a patient for liver transplantation is complex and seeks to determine whether a candidate would benefit from a transplant, whether there are alternative therapies available, and whether the predicted outcome is good enough to justify use of this scarce resource in this individual.

Workup therefore includes a detailed history and physical exam. Full laboratory evaluation is appropriate for patients, considering the magnitude of the operation. Cardiac and pulmonary workup is similarly essential, including stress testing and pulmonary function tests in patients with appropriate risk factors. All screening testing should be up to date, including mammography, colonoscopy, prostate cancer screening, and so forth.

Liver transplantation requires long-term follow-up and medications to prevent rejection and other complications. For this reason, adequate financial and social support must be available to the recipient. Patients in the United States meet with financial coordinators as well as social workers to ensure that they can adequately care for the organ postoperatively. This also assesses risk of recidivism in patients with a history of alcohol or other substance abuse.

SURGICAL CONSIDERATIONS

The major steps of the liver transplant operation are pictured in Fig. 53.3. Many techniques are used; here, we will outline a relatively common general approach. Access to the abdomen is generally obtained using a right subcostal incision and either a midline extension or a left subcostal extension, and sometimes both. Often, portal hypertension is severe, occurring in combination with severe coagulopathy. Care must be taken to prevent exsanguinating hemorrhage. Portal dissection involves ligating the right and left branches of the hepatic artery and transecting the bile duct high in the hilum. Ligation of lymphatics leaves only the intact portal vein for later transection before excision of the liver. The triangular and coronary ligaments are lysed. In an orthotopic placement, the inferior vena cava is encircled above the renal veins and the suprahepatic cava above the hepatic veins in preparation to remove the entire cava. The recipient liver is removed with the retrohepatic cava, and the donor liver is then placed with the donor cava anastomosed to the recipient cava both above the renal veins and below the diaphragm. In the piggyback technique, the caudate is dissected off the retrohepatic cava, leaving the recipient cava intact. The donor cava is anastomosed to the cloaca fashioned using the confluence of the three hepatic veins. Once this is done, the liver is perfused with saline to remove the potassium contained in the preservation solution. The portal vein anastomosis is performed, followed by the hepatic artery and then bile duct, usually in a duct-to-duct fashion (see Fig. 53.3).

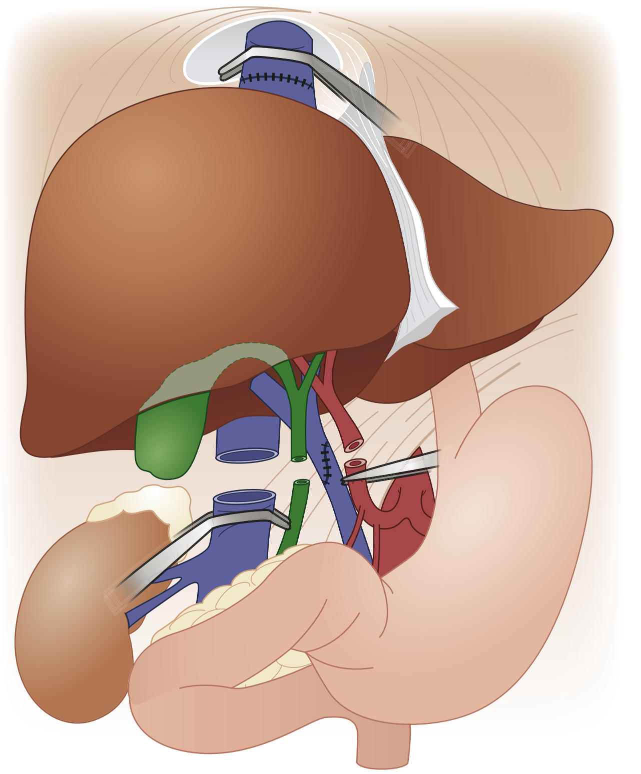

FIGURE 53.3 Steps of the liver transplant operation.

Major hemodynamic shifts occur during the operation. Patients with cirrhosis typically have very low systemic vascular resistance and can quickly become hypotensive with blood loss. Either total caval occlusion using the orthotopic technique or hepatic vein occlusion using the piggyback technique diminishes blood flow to the heart, causing hypotension and increased renal vein pressure, leading to kidney injury. After the liver is implanted, reperfusion leads to a massive bolus of volume to the right heart on opening the cava, which can lead to right heart strain or even failure, which can be life threatening.

In recipients with portal vein thrombosis, first attempts should be to open the vein with thrombectomy catheters and thromboendovenectomy if needed. If this fails, inflow can be obtained from the superior mesenteric vein, nearby varices, and even the left renal vein in patients in whom there is significant splenorenal shunting. For arterial inflow, much of the splanchnic circulation can be used, as can grafts from the suprarenal or infrarenal aorta. Difficult biliary anastomoses can be managed with a Roux-en-Y technique or even direct choledochoduodenostomy. A particularly difficult problem is trying to place a large liver into a small recipient. If the right lobe is very large, it can be difficult to perform the portal anastomosis. Similarly, if the liver is too large in the dorsal-ventral direction, the donor portal vein can lie on top of the recipient portal vein in a fashion where it cannot be cut back far enough to permit anastomosis. In this case, alternative inflow must be sought.

POSTOPERATIVE MANAGEMENT

After a complex surgery with significant hemodynamic derangements, good postoperative management is essential to ensure optimal outcomes. Liver transplantation creates some specific challenges.

Given the hemodynamic changes, patients often come out of the operating room after receiving a significant amount of fluid and blood products. It is critical to have a good sense of the patient's total body volume and intravascular volume. Most patients will be total volume overloaded, but intravascular volume can be low, normal, or high. The best way to determine total body volume status is an accurate patient weight, taking into account preoperative ascites. If the patient is massively volume overloaded but hypotensive, a vasopressor may mitigate the need for massive ongoing fluid resuscitation. Pulmonary artery catheters or noninvasive echocardiographic assessment may help determine intravascular volume to guide decision-making around fluids. Once the blood pressure is normalized, restoring whole body euvolemia is an important goal to prevent soft tissue and pulmonary edema. Volume management is complicated by potential ongoing bleeding and acute renal injury, which is common. Very careful attention must be paid to these possibilities.

Respiratory management consists of extubation as soon as feasible, with the understanding that many patients will be severely debilitated and may not be able to perform the work of breathing. In these cases, early tracheostomy is indicated.

Feeding should begin as early as is safe, and there should be a low threshold for placing a feeding tube should the patient demonstrate an inability to consume adequate calories after normal gastrointestinal (GI) function returns. Early ambulation and incentive spirometry are critical, and early discharge should be a goal to prevent nosocomial infection.

Most programs will use drains for additional fluid and to diagnose bile leaks. These should be inspected multiple times a day for output and color.

COMPLICATIONS AND THEIR TREATMENT

Regarding early complications, careful attention to the patient in the immediate postoperative setting is essential to ensure optimal outcomes. Frequent assessment of graft function is essential, and quick action must be taken when indicated. Postoperative hypotension can be caused by many factors, but bleeding must always be considered. Abdominal drains will usually, but not always, help establish this diagnosis. Drains can become clotted or sequestered from areas of massive hemorrhage. Frequent hematocrit checks should be obtained. Ongoing hemorrhage requiring continuous blood replacement is generally an indication to return to the operating room. The exception may be a patient with severe coagulopathy and or hypothermia, who may benefit from a longer observation period with factor replacement and warming to determine if the bleeding is surgical in nature. A good practice is to set a threshold transfusion limit, after which abdominal exploration is considered. In addition, patients who develop compartment syndrome must return to the operating room.

Primary nonfunction is a serious complication requiring retransplantation. The most common causes are an unrecognized procurement error; use of certain types of higher-risk grafts (fatty, fibrotic, DCD); or arterial complications after the transplant, such as hepatic arterial thrombosis. Typically, the patient will not wake up, the lactate will remain very high, bilirubin will continue to rise, and the AST and ALT will rise into the range of 5000 to 10,000 IU/L. In these cases, an ultrasound should be obtained to interrogate the artery, and plans should be made for urgent retransplantation.

Arterial complications not producing primary nonfunction occur in approximately 2% to 4% of patients.[42] This usually manifests as increased AST and ALT, elevated bilirubin, and poor synthetic function with elevated INR. Arterial stenosis or thrombosis can be diagnosed on ultrasound or contrast CT and must be

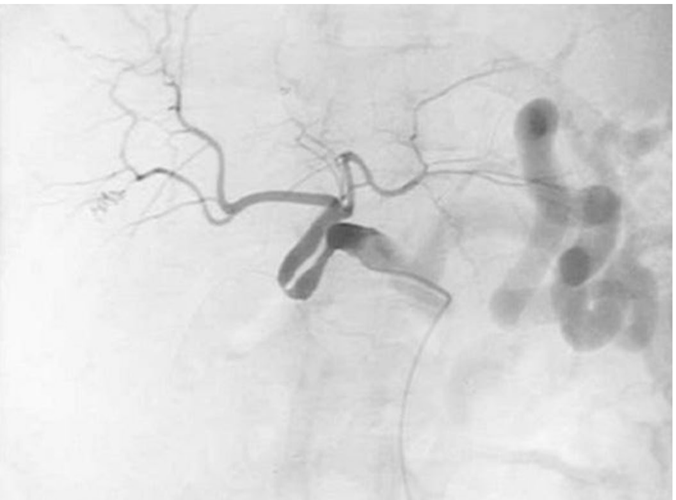

FIGURE 53.4 Hepatic artery stenosis demonstrated by arteriogram.

addressed as soon as possible if discovered. Early arterial thrombosis, even if not associated with primary nonfunction, should lead to relisting for transplantation (Fig. 53.4).

Portal vein stenosis or thrombosis may present with normal liver function tests and synthetic function. Over time, however, these patients develop signs and symptoms of portal hypertension and require intervention. Portal stents are often successful in these situations.

Biliary issues are the most common complication in the postoperative period and occur in approximately 20% of patients. This can present as bile in the drain in the case of a leak or in a patient who returns with a biloma. Stricture leads to increased bilirubin and alkaline phosphatase. Modern management of bile duct issues employs endoscopic management for stent placement and dilations. Early major biliary issues should prompt an ultrasound to ensure vessel patency and reoperation to check for bile duct ischemia and to consider reanastomosis, possibly as a Roux-en-Y reconstruction.

Rejection typically presents with elevated liver function tests and is diagnosed on biopsy, characterized by portal inflammatory infiltrate, bile duct injury, and endotheliitis. In many cases, mild rejection can be treated by raising the immunosuppression level and bolus steroids. More severe rejection may require antibody therapy.

Recurrent hepatitis C is becoming much less common with the advent of direct-acting antiviral therapy.

Late complications include arterial or portal venous structuring, bile duct strictures, and opportunistic infections. Chronic rejection is poorly understood and often leads to the need for retransplantation. Chronic immunosuppression often leads to renal dysfunction and increased risk of certain types of cancer, especially skin cancer associated with sun exposure.

IMMUNOSUPPRESSION

Liver grafts are recognized by the recipient as foreign based on major histocompatibility complex antigens. Hepatocytes express low levels of class I antigen and no class II antigen. During ongoing immune surveillance, T cells recognize the graft as foreign and initiate an immune response. Distinct from renal transplantation, liver transplantation does not require matching between donor and recipient HLA, although there is some concern that the effect of HLA mismatch may be greater than previously appreciated.

Modern immunosuppression offers a variety of classes of agents. Induction agents, if used, are administered at implantation. Choices include anti-thymocyte globulin, an anti–T-cell antibody that binds to and depletes T cells, delivering potent and relatively nonspecific immunosuppression. These are very potent agents that can increase the rate of infection. Basiliximab is an antibody to the interleukin-2 (IL-2) receptor, which blocks IL-2 signaling and is not as immunosuppressive as anti-thymocyte globulin.

Maintenance immunosuppression generally involves agents of three different classes. Steroids inhibit transcription of cytokines, the most important of which is IL-2, which downregulates the immunologic response to antigen. They also inhibit T-cell migration. Side effects are multiple and varied and include hypertension, fluid retention, cataracts, osteoporosis, diabetes, and increased risk of infection. Mycophenolate mofetil inhibits purine synthase, which decreases proliferation of T and B cells. The major side effect is GI upset. Calcineurin inhibitors block signal 2, which is required for T-cell activation. Calcineurin itself is a calcium-dependent phosphatase in T cells. Side effects include hypertension, renal toxicity (which can lead to renal failure), and lipid abnormalities.

The mainstay of immunosuppression for liver transplantation is tacrolimus, with over 90% of liver transplant recipients receiving this drug with mycophenolate and/or steroids. The practice of using induction agents, which have been shown to decrease acute rejection, has increased over time, and they are currently given to approximately 30% of patients.[1] The incidence of acute rejection by 1-year posttransplant is around 10% to 15% among patients using a T-cell–depleting agent and/or IL-2 receptor antibodies for induction.

LIVING DONOR LIVER TRANSPLANTATION, INCLUDING DONOR SELECTION

LDLT arose from the intersection of an improved understanding of segmental liver anatomy, technical advances in hepatic parenchymal transection, and urgency resulting from the inadequate supply of deceased donor liver allografts. LDLT draws on the ability of the liver to regenerate. A portion of liver with sufficient quality and mass, when provided with adequate arterial and venous inflow, as well as venous drainage, will re-create adequate mass to meet the metabolic demands of both donor and recipient. The first LDLT consisted of an adult segment II/III graft that included the left hepatic vein, left hepatic artery, left portal vein, and left hepatic duct that was transplanted into a small child. The field quickly developed to allow for adult-to-adult liver transplantation with right lobe grafts consisting of segments V/VI/VII/VIII, along with the right hepatic veins, right hepatic arteries, right portal veins, and right hepatic ducts and left lobe grafts consisting of segments II/III/IV along with the left hepatic vein, left hepatic arteries, left portal vein, and left hepatic ducts. The increase in the number of LDLTs has led to a better understanding of both recipient selection and donor risk, with significant improvements in patient and graft survival.

Donor

The safety of the donor is of paramount importance. Increased experience with LDLT in several high-volume centers helped define general criteria to maximize donor safety. Specifically, the donor should be left with an adequate amount of hepatic mass to ensure full recovery postoperatively. Donors with acute or chronic liver diseases or extrahepatic diseases that may subsequently impair regeneration are excluded from becoming living liver donors. Donors should undergo a thorough medical and psychosocial evaluation to ensure that they are able to donate and recover from surgery safely. A donor should be left with a residual liver volume of no less than 30%.[43] This may be increased if the donor is older or has hepatic steatosis. Although laparoscopic live liver donation has been reported, most centers perform an open hepatectomy.[44] Donation is associated with a mortality rate of 0.2%.[43] Forty percent of donors will experience at least one complication within the first year after donation. The most frequent complications include infection (13%–15%), bile leak/biloma (7%–9%), reoperation (2%–3%), and hernia (11%–16%).[43] Despite both short- and long-term complications, most donors would choose to donate again.

Recipient

Successful living donor transplantation requires a liver allograft of adequate parenchymal mass to support the recipient's metabolic needs, as determined by the donor graft-recipient weight ratio (GRWR). Although successful liver transplantation has been performed with living donor grafts resulting in GRWR as low as 0.5%, the risk of morbidity and mortality due to small-for-size syndrome significantly increases with decreasing GRWR. Small-for-size syndrome develops when the amount of functioning transplanted liver parenchyma is inadequate to support the recipient; it manifests with jaundice, coagulopathy, ascites, encephalopathy, and renal impairment that may progress to death. Retransplantation with a larger allograft may be necessary.

A GRWR of 0.8% to 1% is generally accepted as safe; however, donor liver quality and recipient degree of illness both affect the minimum safe GRWR. Donor steatosis, donor age older than 50 years old, and high recipient MELD score frequently necessitate higher GRWR up to or more than 1%.[43] Ensuring adequate hepatic arterial and portal venous inflow to the live donor allograft is of critical importance for immediate graft function and subsequent graft hypertrophy. Hepatic parenchymal mass is regulated based on portal vein flow, and inadequate portal flow resulting from portosystemic shunting can be deleterious to allograft regeneration and perpetuate graft failure. Alternatively, exposure of a healthy liver allograft to sudden and persistent portal hypertension can lead to centrilobular injury and small-for-size syndrome.

LDLT is technically challenging because of the microvascular and biliary reconstructions necessary between the donor graft and recipient. The biliary reconstructions are especially prone to complications, with biliary stricture occurring in nearly 30% of recipients. Despite the challenges, LDLT is currently associated with a 1-year patient survival of almost 93% and is an important and lifesaving option.[43]

PEDIATRIC LIVER TRANSPLANTATION

The indications for pediatric liver transplantation are generally grouped into diseases leading to cirrhosis, inborn errors of metabolism, primary hepatic malignancies, and ALF. Biliary atresia is the most common cause of end-stage liver disease in children and accounts for one-third of all pediatric liver transplants. It is a congenital disease of unknown etiology that leads to progressive fibroinflammatory obliteration of the biliary tree and the rapid development of cirrhosis. A diagnosis of biliary atresia should be suspected in all infants with persistent neonatal jaundice. Early intervention within the first several months of life is associated with superior outcome.[45] Reestablishing adequate biliary-enteric drainage before the development of end-stage liver disease is critical. This is typically accomplished by surgical anastomosis of the intestine to the biliary tree at the hepatic hilum. Pioneered by Kasai in the 1950s, the procedure is known as a *hepatic portoenterostomy* and has long-term success when the disease process is limited to the extrahepatic biliary tree.[46] Unfortunately, most children with biliary atresia have disease involvement of the intrahepatic biliary tree, with progression of cirrhosis and death without liver transplantation.[47] Failure to normalize bilirubin at 3 months after hepatic portoenterostomy is predictive of the need for salvage liver transplantation, as are growth failure and recurrent bouts of cholangitis.[48] Nearly half of children with biliary atresia treated with portoenterostomy will need a liver transplant by 2 years of life. Other diseases, such as autoimmune hepatitis and PSC, can also lead to cirrhosis requiring liver transplantation in children.

Unlike adult liver transplantation, pediatric liver transplantation is frequently performed for indications beyond the treatment of end-stage liver disease. The liver is the major site of nitrogen metabolism in the body, and inherited genetic abnormalities involved in any aspect of the urea cycle or amino acid catabolism can lead to the accumulation of toxic metabolites and neurologic injury. Significant enzymatic dysfunction within the urea cycle of either N-acetylglutamate, carbamoyl phosphate synthase I, ornithine transcarbamylase, or argininosuccinate lyase deficiency impairs the body's ability to dispose of nitrogenous waste through the conversion of ammonia to urea. The neurotoxic hyperammonemia that ensues, particularly in the interval shortly after birth, causes the rapid development of lethargy, cerebral edema, seizures, and death. Other enzyme deficiencies within the urea cycle, including those of argininosuccinate synthase or citrin with resultant citrullinemia, arginase with resultant hyperargininemia, and ornithine translocase deficiency with resultant hyperornithinemia and homocitrullinuria, result in more insidious hyperammonemia and progressive neurologic injury. Similarly, enzymatic dysfunction in amino acid catabolism, as seen in maple syrup urine disease, methylmalonic acidemia, propionic acidemia, and tyrosinemia, results in the accumulation of certain amino acids and their metabolites, with resultant cellular toxicity and neurologic injury. Children with inborn errors of nitrogen metabolism are particularly vulnerable to neurologic injury resulting from the metabolic stress associated with growth, injury, or infections. Routine viral infections of childhood, including common colds or influenza, can be life-threatening events. The synthetic function of the liver in patients with inborn errors of metabolism is normal, and liver transplantation is performed to provide normal enzymatic function and minimize or arrest further neurologic injury. Early liver transplantation minimizes or arrests neurologic injury.[49]

Liver transplantation treats primary malignancies of the liver, including hepatoblastoma and HCC. Hepatoblastoma arises from fetal or embryonal hepatocyte progenitor cells and is the most common primary pediatric liver malignancy. It is often diagnosed in children less than 3 years of age when they present with abdominal distention, feeding intolerance, or abdominal pain. The goal of treatment of hepatoblastoma is complete surgical resection. The PRETEXT (pretreatment extent of disease) classification is used to stage the extent of hepatic involvement and the likelihood of successful treatment with partial hepatectomy.[50] Although most hepatoblastomas can be successfully treated with partial hepatic resection, approximately 10% are surgically unresectable and benefit from liver transplantation, which provides for a 3-year survival of 75%, with most mortality secondary to disease recurrence.[51] HCC is very rare in the pediatric population and has a different pathology than that in adults. Excellent long-term survival approaching 80% at 5 years is reported with liver transplantation for HCC even when patients exceed the Milan Criteria.[52]

Most pediatric recipients who undergo orthotopic liver transplantation are younger than 5 years of age, and many receive a deceased donor whole liver allograft. However, the number of children needing a liver transplant greatly exceeds the number of pediatric whole liver deceased donors. This imbalance between the supply of size-appropriate pediatric deceased donors and demand of pediatric recipients necessitated the development of techniques for liver transplantation using reduced-size adult allografts. The introduction of deceased donor split liver allografts in 1998 allowed the transplantation of infants and small children using the left lateral section of an adult liver based on the vasculobiliary anatomy of the left lobe. LDLT further increased liver allograft availability for all pediatric patients with end-stage liver disease. The transplantation of left lateral segment and live donor grafts necessitates the use of a cava-preserving technique. The vascular anastomoses in infants and small children have an increased complication rate, and microvascular techniques and anticoagulation are routinely used to minimize thrombotic events. Long-term results for pediatric liver transplantation are excellent, with a 5-year graft survival of 85% for biliary atresia and by a 5-year graft survival slightly above 75% for hepatoblastoma and ALF (Fig. 53.5).[1]

New Technologies, Treatment Paradigms, and Advances

Machine Perfusion

Machine perfusion is an old technology made new again. It was pioneered by many surgical teams, such as Folkert Belzer's at the University of California, San Francisco (UCSF), in the late 1960s for short-term kidney preservation and transportation and was even described by Thomas Starzl for short-term liver preservation during the recipient operation. However, cost, safety, and contemporaneous advances in static preservation solutions that yielded some of the first reliable preservation solutions, such as Euro-Collins, prevented any serious adoption of the technology. After moving to the University of Wisconsin, Dr. Belzer and his colleague Dr. Southard would also help create a benchmark preservation solution in the late 1980s, solidifying cold storage as the standard of care.

Over 30 years later, clinical investigation of machine perfusion devices gained renewed interest, with groups in the United States and Europe publishing clinical series of liver transplants after hypothermic oxygenated machine perfusion. Groups in the UK and Netherlands began to publish trial series using normothermic machine perfusion devices before liver transplantation. Worldwide interest in machine perfusion has exploded in the last 10 years; many recognize its potential to recover, test, and possibly rehabilitate marginal livers before transplantation, helping reduce the organ shortage. Mechanisms of how machine perfusion benefits grafts are still debated, but many believe machine flow maintains sinusoidal endothelial cell integrity; oxygenation repletes mitochondrial adenosine triphosphate (ATP) stores; and in the case of normothermic machine perfusion (NMP), body temperature enables metabolic function and nutrient supplementation during preservation.[53] Hypothermic oxygenated perfusion (HOPE) has recently been shown in a randomized trial to have

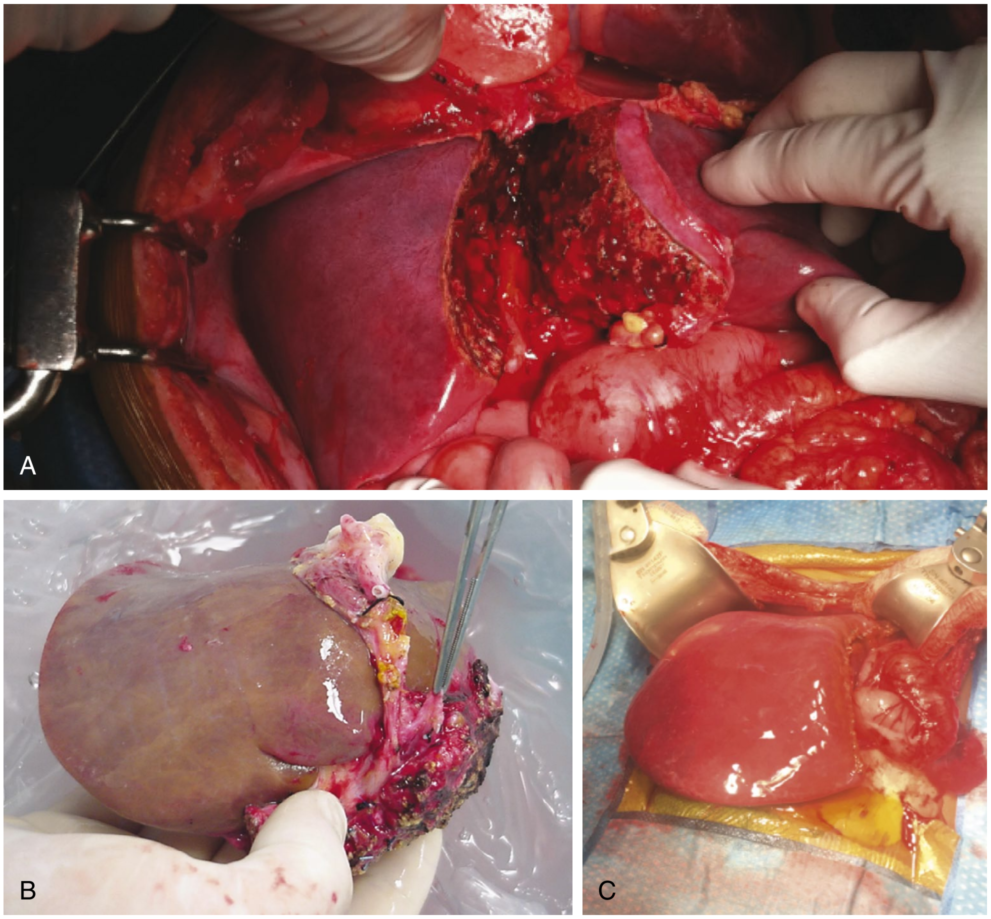

FIGURE 53.5 Split liver transplant for a child. (A) In situ resection of live donor graft. (B) Segment prepared for transplant. (C) Graft reperfused in recipient.

superior outcomes to static cold storage, with lower rates of early allograft dysfunction and a lower incidence of nonanastomotic biliary strictures, especially in DCD donors.[54] Randomized trials in NMP have also shown excellent outcomes and promising improvement in recovery of marginal donor organs.[53] There is ongoing investigation of the use of NMP for these marginal donors because the body temperature conditions enable metabolic assessment of liver grafts and enable improved logistics for transplant centers because perfusions can occur overnight, allowing surgeons to rest before cases (Fig. 53.6).[55] In addition to machine perfusion devices, there is growing literature on the use of extracorporeal membrane oxygenation (ECMO) devices on DCD donors before organ procurement in a technique called *normothermic regional perfusion* (NRP). The donor is cannulated for ECMO after withdrawal of support, and either the abdomen or the chest and abdomen are perfused for a period of 2 to 4 hours before procurement of abdominal and/or thoracic organs. This technique has gained popularity in many European countries, but there is still ethical debate on whether its use should be expanded in the United States, where not all regions of the country currently allow it.

Transplant Oncology

The indications for liver transplantation covered previously are numerous. As surgical techniques for both donor and recipient operations improve and knowledge of optimal preservation methods increases, so will the indications for an allograft. The concept of transplant oncology is an expansion of the multidisciplinary team for hepato-biliary tumors. It was born of our increased abilities to safely resect diseased liver tissue as well as a recognition that patients with liver tumors require a more coordinated and thoughtful approach to management that may also include transplantation. Over the past 30 years since the Milan Criteria, it has been feasible to safely transplant highly selected patients with unresectable colorectal liver metastases, intrahepatic and perihilar cholangiocarcinomas, neuroendocrine liver metastases, and hepatic hemangioendothelioma. Care for these complex hepato-biliary tumors continues to progress, and multidisciplinary teams must include transplant surgery and medicine to extend the margins of traditional surgical oncology and determine how transplant immunology can be leveraged against tumor biologies that enable liver transplantation as cure.[56]

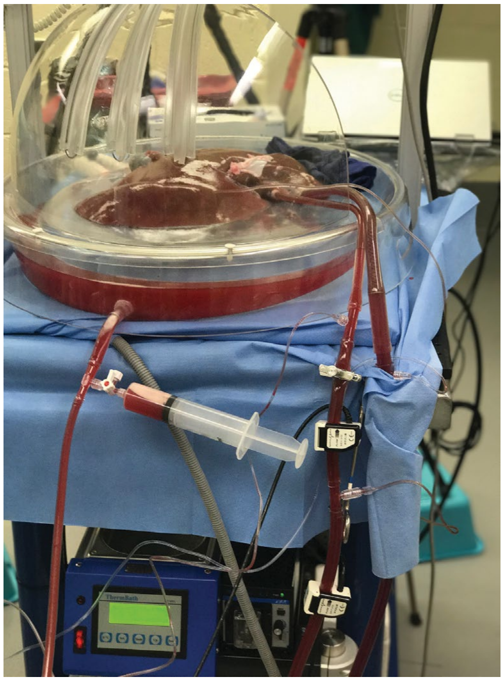

FIGURE 53.6 Machine perfusion of a liver.

Xenotransplantation

As with many ideas in transplantation, xenotransplantation is not entirely new. Starzl undertook the first xenotransplant of nonhuman primate to human liver in 1966, which was unsuccessful. It was tried again in the 1990s by a few surgeons (including Starzl once more), with short-term success on the order of days. Since that time, decades of preclinical work in immunology and genomics have allowed for exponential growth in xenotransplantation. Specifically, the use of CRISPR-Cas9 to create the genetically engineered α1,3-galactosyltransferase KO (GalT-KO) pigs has successfully taken the field from small animal studies to clinical research protocols in humans, with promising results for kidneys.[57] With this same technique, the first gene-edited pig liver was transplanted in China in March of 2024. Despite this progress, our scientific understanding of xenotransplantation has outpaced our moral and ethical understanding. Much work must be done to understand all the true costs and risks for both nonhuman donors and human recipients if this breakthrough is to become future clinical practice.

Summary and Future Perspectives

INTRODUCTION

Pancreas transplantation was the first treatment to successfully restore euglycemia with endogenous insulin production in patients with type 1 diabetes mellitus (T1DM). The early outcomes of whole organ pancreas transplantation were dismal. However, advances in surgical techniques, organ preservation, and immunosuppression over time have led to improved outcomes for pancreas transplant recipients, who now experience 85% to 90% 1-year graft survival and greater than 95% 1-year patient survival.[1] The remainder of this section will focus on providing a brief history of pancreas transplantation and related landmark events, which are summarized in Fig. 54.1.

The treatment of diabetes was revolutionized by the discovery of insulin by the Canadian research team led by Frederick Banting and Charles Best in 1921.[2] The discovery of this essential pancreatic hormone combined with performance of the first successful kidney transplant in 1954 led to the conceptualization of pancreas transplantation as a way to restore endogenous insulin production in T1DM. In 1966, the first human pancreas transplant was performed in combination with a kidney transplant for a patient with T1DM and end-stage renal disease (ESRD) by a team led by Richard Lillehei and William Kelly at the University of Minnesota in Minneapolis.[3] The procedure was performed using a duct-ligated segmental pancreas with cobalt-60 irradiation to limit pancreatic exocrine secretions. At that time, effective immunosuppressive agents were still not available, so a combination of azathioprine and prednisolone was employed. The pancreas graft was eventually explanted as a result of graft pancreatitis, thought to be secondary to duct ligation and rejection, and ultimately, the patient succumbed 13 days after transplant. This first case highlighted difficulties in exocrine management and the need for improved immunosuppression and organ preservation in pancreas transplantation. Soon after the first, a second pancreas transplant was performed. This time, the recipient received a whole pancreas graft, including the duodenum, with construction of a cutaneous duodenostomy to manage exocrine secretion. However, the transplanted pancreas failed after 2 months as a result of rejection involving the duodenum, and the patient succumbed to sepsis 4 months posttransplant.[4] After several failed attempts relying on enteric exocrine drainage, segmental pancreas transplantation gained popularity up until the mid-1980s in order to avert implanting the highly antigenic duodenum. During this period, procedures such as pancreatic ductal ureterostomy[5] and neoprene polymer injection to permanently occlude the pancreatic duct[6] were employed. These techniques achieved up to 50 and 29 months of graft survival, respectively. Ultimately, bladder drainage with a duodenocystostomy replaced these other experimental techniques and became the standard method for managing exocrine secretions in the late 1980s.[7,8] However, as experience accumulated over the ensuing decades and urologic complications mounted, surgeons began to revisit enteric drainage approaches to managing exocrine secretions with duodeno-intestinal anastomoses in the mid-1990s.[9]

It is also noteworthy that the first living donor pancreas transplantation was performed in 1979, primarily to offer a preemptive opportunity for pancreas transplantation and minimize rejection rates by using related donors.[10] Another surgical consideration for pancreas transplant surgeons at this time was whether venous

drainage should occur through the portal or systemic venous system. For this reason, a portal venous drainage technique was employed, particularly in the 1980s, to create a more physiologic flow of insulin and prevent pseudohyperinsulinemia, although the causal relationship and clinical implications for posttransplant outcomes of this phenomenon were not completely understood.[11] Ultimately, portal venous drainage demonstrated no clear benefit in pancreas transplant outcomes; thus, systemic venous drainage of the pancreas graft remains the preferred method of venous drainage, particularly for its surgical simplicity.

Increasing volumes of organ transplantation led to the need for better preservation of organs for transport over longer distances. The first commercially available cold storage preservation solution was Collins solution, developed in 1969. Modifications to this formulation were made to prolong organ storage time, leading to the production of Euro-Collins solution by 1980. Soon afterward in the late-1980s, the University of Wisconsin (UW) solution was developed, and this solution and its competitor, histidine-tryptophan-ketoglutarate (HTK) solution, became the dominant cold storage solutions for abdominal organ preservation.[12] These advances in organ preservation allowed for an expansion in use of pancreases for transplant because they could be stored and transported over long distances and for longer periods of time.

As was the case for the entire field of organ transplantation, a major step forward in pancreas transplant outcomes came after the approval and routine use of cyclosporine A (CsA) in 1983.[13] The introduction of this agent into maintenance immunosuppression regimens dramatically reduced rates of allograft rejection. After this revolutionary advance in immunosuppression, a pancreas transplant without the duodenum employing pancreaticocystostomy[7] and a whole pancreas grafting with graft duodenocystostomy[8] were developed in 1983 and 1987, respectively. These successes led to bladder drainage becoming the main means of exocrine drainage until the mid-1990s. The ability to measure amylase level in urine as a biomarker of rejection conferred an important advantage in an era when acute pancreas graft rejection rates were still 50% to 70% or greater in the first year posttransplant. Nevertheless, bladder drainage is not a physiologic pathway for exocrine pancreas drainage, and the technique thus caused both acute and chronic complications, such as urinary tract infection, chemical cystitis and urethritis, and refractory acidosis, which often required surgical conversion to enteric drainage. For this reason, the mode of exocrine drainage of the pancreas was reevaluated, leading to a paradigm shift to enteric drainage for pancreas transplants in the mid- to late-1990s. At about the same time, other major immunosuppressants, tacrolimus and mycophenolate mofetil in particular, were introduced to the field of organ transplantation for more effective maintenance immunosuppression.[14,15] Finally, the recognition that early lymphocyte depletion improved transplant outcomes stimulated the development and clinical implementation of induction immunotherapy agents such as antithymocyte globulin and alemtuzumab, further reducing rates of early pancreas allograft loss from rejection.[16,17]

As another major step forward in organ transplantation in general, the single human leukocyte antigen (HLA) beads assay was developed by Paul Terasaki and his colleagues, which eventually enabled the prediction of physical cross-match results by a virtual cross-match, helping streamline organ allocation.[18]

The evolution of pancreas transplantation into the practice we know today is closely aligned with advances in surgical technique, organ preservation, and immunologic management. Although other major therapeutic options, such as islet transplantation and continuous glucose monitoring technology, were developed and clinically applied in 1990 and 2000, respectively,[19,20] pancreas transplantation is still recognized as the most durable and effective therapeutic option for restoring endogenous insulin production. The remainder of this chapter will focus on the current practice of pancreas transplantation, its outcomes, and what directions this field might take in the future to further improve outcomes (see Fig. 54.1).

PATIENT SELECTION

Historically, pancreas transplantation had been reserved for patients with T1DM because these patients had their islet mass destroyed by autoimmunity and were expected to benefit from restoration of islet mass by the pancreas graft while also reducing the threat of recurrent autoimmune destruction of islets by using immunosuppression and HLA mismatching. Patients with type 2 diabetes mellitus (T2DM) were traditionally not expected to benefit from pancreas transplantation because of a concern for reduced rates of achieving insulin independence as a result of peripheral insulin resistance and metabolic syndrome. However, pancreas transplantation for lean T2DM patients is on the rise, with favorable outcomes in terms of patient survival, graft survival, and glycemic control.[22] Despite these successes, there remains a paucity of data to understand the limits to successful outcomes in this population with regard to pretransplant insulin requirements, body mass index, and fasting C-peptide levels.

The majority of pancreas transplants are performed in combination with a kidney transplant as a simultaneous pancreas-kidney (SPK) transplant for patients with insulin-dependent diabetes mellitus and ESRD. In addition to meeting the requirements for kidney transplantation, patients should be requiring treatment with insulin. Decisions about moving forward with SPK transplantation versus kidney transplant alone or pancreas transplant after kidney transplant (PAK) are based on factors such as availability of a compatible, high-quality living donor kidney (LDK) or, in the absence of an LDK, the estimated wait time on dialysis as well as comorbidities and surgical risk associated with SPK transplant. Which option is best should be individualized and determined through multidisciplinary discussions with patients. Patients with insulin-dependent diabetes seeking pancreas transplant alone (PTA) should have documented significant complications of insulin therapy, such as impaired awareness of hypoglycemic events, including severe hypoglycemic events, or consistent failure of exogenous insulin therapy as well as normal stable renal function without evidence of significant proteinuria or diabetic nephropathy.[23] Another less frequent indication for pancreas transplant is endocrine and exocrine insufficiency associated with cystic fibrosis[24] or pancreatectomy. Other less common indications for pancreas transplantation include those who have undergone total pancreatectomy for chronic pancreatitis, with or without autoislet transplantation; those who have lost endogenous insulin production; and those who are on exogenous insulin therapy.[25] In these cases, the pancreatic allograft can treat both endocrine and exocrine insufficiencies.

All potential pancreas transplant recipients should undergo a full evaluation, including a thorough history and physical examination, to identify any existing medical conditions that may require optimization and prior surgery that would influence their candidacy for transplant. Contraindications to pancreas transplant include active malignant disease, active infection, severe peripheral vascular disease, severe cardiac or pulmonary disease, active IV drug abuse, and significant psychosocial barriers to compliance with posttransplant medical management. Laboratory evaluation should include serum chemistries, liver function testing, complete blood count, coagulation profile, urinalysis, fasting C-peptide, hemoglobin A1c (HbA1c), and autoantibody serologies as well as serology testing for hepatitis B and C, cytomegalovirus (CMV), Epstein-Barr virus (EBV), varicella-zoster virus (VZV), syphilis, human immunodeficiency virus (HIV), and tuberculosis. Imaging should include a chest x-ray and abdominal and pelvic CT imaging to evaluate the candidate's iliac vasculature and anatomy for surgical planning purposes. Cardiac risk stratification is an essential component of the evaluation because there is a high rate of silent atherosclerotic disease in the diabetic-uremic individual. All patients should undergo an electrocardiogram of the heart and cardiac stress testing at a minimum. In addition, all patients over age 50 or those with risk factors such as angina symptoms, smoking history, and iliac vascular disease should be considered for a resting echocardiogram and coronary angiography to evaluate for any intervenable ischemic cardiac disease before transplant. Physical examination should include pulse examination, particularly of the femoral, posterior tibial, and dorsalis pedis pulses, to gauge the degree of peripheral vascular disease that requires further workup. A psychosocial evaluation should also be performed to determine a candidate's social support and mental status before transplant to ensure appropriate resources are available to maintain compliance with medications and clinical follow-up posttransplant. Open wounds and amputations should be noted and ideally healed before transplantation. A frailty assessment is valuable as well.[26]

DONOR SELECTION

Donor selection for pancreas transplantation begins with a screening of donor characteristics. The pancreas can be procured and used successfully from both donation after brain death (DBD) and donation after circulatory death (DCD) donors, with similar outcomes, particularly with the use of newer technologies such as normothermic regional perfusion in the case of DCD.[27,28] However, successful donation of pancreas from DCD is generally limited to donor functional warm ischemia times of less than 30 minutes. The pancreas donor risk index (PDRI) is a useful tool for predicting pancreas graft outcomes, particularly with regard to early technical and ischemia-reperfusion injury–related outcomes, taking into account donor age, sex, terminal creatinine, body mass index, race, height, cause of death, type of donor (DBD or DCD), cold ischemia time, and whether or not is the organ will be used as a pancreas after kidney transplant.[29] Other high-risk factors to consider in the donor are HbA1c and past medical history of diabetes or prediabetes; obesity; traumatic injury to the pancreas, duodenum, or spleen; evidence or history of pancreatitis; chronic alcohol use; and any abnormal lesions in the pancreas, duodenum, or spleen. Evaluation of the pancreas during and after procurement on the back table is integral for a successful outcome and requires significant surgical experience. The ideal pancreas organ should be free of significant adipose tissue within the parenchyma. When palpated, the parenchyma should be soft and free of nodularity and able to be folded over on itself (i.e., supple). The parenchyma should be free of saponification or hemorrhage, and the duodenum should be free of injury. The superior mesenteric artery (SMA) and splenic artery should be of adequate size for reconstruction with donor iliac Y graft, usually at least 3 mm in size. It is important to note during procurement the presence of any aberrant arterial anatomy, such as inferior pancreaticoduodenal arteries arising from a replaced right hepatic artery. In this situation, the pancreas may be used; however, it is important to evaluate flow by flushing the SMA and observing the flush returning out of the gastroduodenal artery (GDA) stump to ensure there is enough collateral blood supply to perfuse the head of the pancreas.

Evaluation of the quality of the donor kidney should also be considered carefully using metrics such as the kidney donor profile index (KDPI) and anatomy of the right and left kidneys in order to choose an appropriate kidney for recipients of SPK transplant. It should also be noted that for higher-risk recipients, it may be wise to choose lower-risk organs so that higher recipient risks and higher donor risks are not stacked together.

PANCREAS PROCUREMENT

Donation After Brain Death

There are several methods to procure deceased donor grafts during multiorgan recovery, with a priority being avoidance of compromising the recovery and use of other organs. Two common approaches include procuring the pancreas separately or en bloc with the liver, emphasizing that an extensive in situ (in the warm) dissection should occur using a no-touch to light-touch technique on the pancreas for the purpose of facilitating a rapid post–cross-clamp extraction and minimizing surgical trauma to the pancreas. First, to decontaminate the duodenum, amphotericin B, nystatin, or povidone-iodine solutions are typically injected through an indwelling nasogastric tube, but this practice has not been determined to be essential. In general, a midline incision from the sternal notch to the pubic bone is made with or without a cruciate extension for internal visualization of abdominal organs. A transverse incision enables better exposure of the tail of the pancreas and spleen. Alternatively, division of the diaphragm bilaterally can facilitate upper abdominal exposure. The infrarenal abdominal aorta just above the bifurcation is accessed and encircled for vascular control early in the operation in case of DBD donor instability and for rapid recovery in the case of DCD donors. The supraceliac aorta is prepared in the thoracic or abdominal cavity for a cross-clamp. Initial visualization of the pancreas is facilitated by entry into the lesser sac and ligation of the gastrocolic omentum and short gastric vessels. Then, via Cattell-Braasch and Kocher maneuvers, the duodenum, head of the pancreas, ascending colon, and small intestine are mobilized. To maximize exposure, the stomach can be divided just proximal to the pylorus by using a gastrointestinal anastomosis (GIA) linear stapler. The pancreas should be palpated and photographed at this stage, and information is shared with the recipient surgical team. If the appearance is not ideal, the organ may be declined at this point. Of note, as the gastrohepatic ligament is divided to approach the supraceliac aorta, care should be taken to avoid injury to an accessory or replaced left hepatic artery. If present, the left gastric artery is preserved, and peripheral branches are divided close to the lesser curvature of the stomach. Furthermore, during the inspection of the hepatoduodenal ligament, if there is a replaced right hepatic artery or the proper hepatic artery arises from the SMA, the procurement method should be discussed with the liver team to determine how to allow for simultaneous safe recovery and preserve perfusion to both organs.

Next, the distal common bile duct is ligated and divided just above the head of the pancreas, and the gallbladder is incised to flush both the gallbladder and the common bile duct with saline. The GDA is also identified and looped. The left renal vein is dissected out and looped. Then the location of the root of the SMA is identified and separated from the surrounding ganglion tissues and encircled with a vessel loop. Ideally, additional time for in situ warm dissection is carried out before cross-clamping and in situ flush. The inferior border of the pancreas is mobilized from the pancreaticocolic ligament with ligatures of the mesentery structures, and the spleen is detached from the retroperitoneum. Then the pancreas is mobilized away from the retroperitoneum, with the spleen being used as a handle and using a no-touch technique. Identification and dissection of the inferior mesenteric vein (IMV) should be carried out to facilitate cannulation for in situ portal venous flushing. Careful dissection of the celiac bifurcation to expose the common hepatic artery and splenic artery, as well as exposure of the portal vein, are valuable to identify points of separation of the pancreas and liver in order to speed organ extraction. It is also important to avoid direct trauma to the pancreas surface or capsular injury during this dissection.
